Fig. 52.

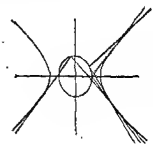

Fig. 53.

gent at any point P (Fig. 51) bisects the angle between PF and PF'. The locus of the foot of the perpendicular from the focus on a moving tangent is the circle on the principal axis as diameter (Fig. 52). The locus of the point of intersection of perpendicular tangents is a circle with radius $\sqrt{a^2 - b^2}$, which will be imaginary if $b > a$ (Fig. 53).

Properties of the Asymptotes. (Fig. 54.) If P is any point of the curve, the product of the perpendicular distances from P to the two asymptotes is constant, $= a^2b^2/(a^2+b^2)$. Also, the product of the oblique distances (the distance to each asymptote being measured parallel to the other) is constant, and equal to $\frac{1}{4}(a^2+b^2)$. If a line cuts the hyperbola and its asymptotes, the parts of the line intercepted between the curve and the asymptotes are equal. The part of a tangent intercepted between the asymptotes is bisected by the point of contact. The triangle bounded by the asymptotes and a variable tangent is of constant area, $= ab$. If a line through Q perpendicular to the principal axis meets the asymptotes in R and S (see Fig. 54), then $\overline{QR} \times \overline{QS} = b^2$. If a line through Q parallel to the principal axis meets the asymptotes in U and V, then $\overline{QU} \times \overline{QV} = a^2$.

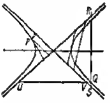

FIG. 54.

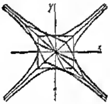

FIG. 55.

Conjugate Hyperbolas are two hyperbolas having the same asymptotes with semi-axes interchanged (Fig. 55). The equation of the hyperbola conjugate to $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$, is $\frac{x^2}{a^2} - \frac{y^2}{b^2} = -1$.

Conjugate Diameters are lines through the center, each of which bisects all the chords parallel to the other—a chord which does not meet the given hyperbola being understood to be terminated by the conjugate hyperbola (Fig. 55). If m_1 and m_2 are the slopes, then $m_1m_2 = b^2/a^2$. Each asymptote, regarded as a diameter, is its own conjugate. If a parallelogram is formed *by tangents drawn parallel to a pair of conjugate diameters, its vertices will* lie on the asymptotes, and its area will be constant $= 4ab$. If a', b' are conjugate semi-diameters, and w the angle between them, then $a'^2 - b'^2 = a^2 - b^2$, and $a'b' = ab/\sin w$.

Equilateral Hyperbola ($a = b$). Equation referred to principal axes (Fig. 56): $x^2 - y^2 = a^2$. NOTE. $p = a$. Equation referred to asymptotes as axes (Fig. 57): $xy = a^2/2$. (See also Fig. 3, p. 174.)

Asymptotes are perpendicular. Eccentricity $= \sqrt{2}$. Any diameter is equal in length to its conjugate diameter.

Calculations of the changes in the pressure, volume, and temperature of air during compression or expansion are facilitated by the diagram Fig. 1, adapted from the "Entropy-Log Temperature Diagram for Air" by Prof. C. R. Richards (*Univ. Illinois Eng. Expt. Sta., Bull.* 63).

In Fig. 1 the vertical lines represent the volume in cubic feet occupied by 1 lb of air. The lines slightly inclined to the vertical represent the absolute pressure in pounds per square inch. The lines at an angle of 45 deg represent temperature in degrees Fahrenheit, and the broken inclined lines represent entropy. These last lines are paralleled in finding the results of an adiabatic change, and if the change follows a $p_1V_1^n = p_2V_2^n$ path, the effects are studied by paralleling lines for various values of n at the lower right-hand corner of the figure, all of which pass through the 400 point on the left of the figure. For example, the adiabatic expansion of 1 lb of air from a pressure of 100 lb abs per sq in. and a temperature of 160 F to a pressure of 14.7 lb abs will result in a final temperature of −100 F. This expansion follows the dotted line of the diagram, but if the expansion followed the equation $p_1V_1^{1.2} = p_2V_2^{1.2}$, the final temperature for any pressure range would be found by following a line parallel to the line marked $n = 1.20$ from the upper to the lower pressure. If such an expansion occurred between 100 lb abs per sq in. and 160 F and 14.7 lb abs, the resulting temperature would be −5 F.

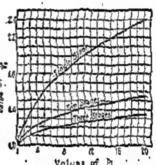

FIG. 2.—Compression Temperatures.

With adiabatic compression, the final temperature T_2 (F abs) is given by the formula $T_2 = T_1\,(p_2/p_1)^{0.283}$ for single-stage compression; by $T_2 = T_1\sqrt{(p_2/p_1)^{0.283}}$ for two-stage compression and perfect intercooling; and by $T_2 = T_1\sqrt[3]{(p_2/p_1)^{0.283}}$ for three-stage. Values of T_2 may be obtained readily from the chart devised by F. W. O'Neill and shown in Fig. 2, in which the ordinates give the factors by which the initial absolute temperature T_1 (F) is to be multiplied to obtain the final absolute temperature T_2 for various ratios of p_2 to p_1 (see also Table 17, p. 315).

BLOWERS AND COMPRESSORS

Rotary blowers are built for air pressures varying from 6 oz to 10 lb or even 12 lb per sq in. The best efficiencies of this type of blower, however, are

The loss in capacity for stage compression will be represented by the following formulas, in which p_1 is the initial and p_2 the final pressure:

$$\text{Two-stage: } C\left[\left(\frac{p_2}{p_1}\right)^{\frac{1}{2\times 1.4}} - 1\right]; \qquad \text{Three-stage: } C\left[\left(\frac{p_2}{p_1}\right)^{\frac{1}{3\times 1.4}} - 1\right]$$

Figure 21 represents graphically the part within the brackets of the preceding equations. Knowing the actual clearance and the pressure range, the effect of this clearance on capacity can be found. For example, with a pressure ratio of $p_2/p_1 = 8$, the chart shows this value for single-stage compression to be 3.3. The capacity for these conditions and a 4 percent clearance will be $1 - (0.04 \times 3.3) = 1 - 0.132$, or 86.8 percent of the piston displacement. Clearances in the larger sizes of compressors vary from 2 to 4 percent; in smaller machines they are greater, being in some cases as high as 5 or 6 percent.

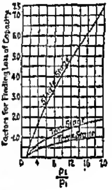

Fig. 21.

The indicator card would be a true method of measuring the volumetric efficiency if the temperature of the air after being drawn into the cylinder were the same as that of the atmosphere and if the pressure at the end of the suction stroke were the same as that of the atmosphere. This is never the case.

The **compression efficiency** is the ratio of the work required to compress adiabatically all the air or gas delivered by the compressor to the work done within the compressor cylinder, as shown by the indicator cards.

Compression efficiency is sometimes expressed in terms of isothermal compression, though this practice is discouraged by the A.S.M.E. in its Power Test Code. Table 4 gives conversion factors or multipliers for converting compression efficiency adiabatic base to corresponding efficiencies based on *isothermal compression with perfect intercooling.*

Table 4. Factor for Converting Compression Efficiency Adiabatic Base to Compression Efficiency Isothermal Base

Ratio of compression	Single stage	*Two stage*	Ratio of compression	*Two stage*	*Three stage*

8.5	0.725	0.869	45.0		0.835

usually secured below 5 lb pressure, but the simplicity of the machine gives it an advantage over compressors of the piston type and frequently warrants its installation for the higher pressures indicated when designed for this purpose. As the machine operates by displacement, it is usually preferred to a centrifugal blower for cupola practice because its positive action will maintain the air supply if the cupola tends to clog. For other uses of air at pressures below 8 oz, the fan is ordinarily more economical.

Blowers of this type may be arranged to give either **constant volume or constant pressure** and to handle either liquids or gases. They consist of a casing containing one or more revolving impellers of various forms of design.

Figure 3 illustrates a cross section of a **Roots blower.** The two impellers are symmetrical and are driven in opposite directions by gears outside the casing. The impellers do not touch each other or the casing, but the clearance is reduced to a minimum in order to reduce slip or leakage. The amount of this **slip or leakage** may be determined by operating the machine with a closed discharge, at a speed sufficient to maintain the required discharge pressure. The amount is usually largest in machines of smallest capacity, *i.e.*, a machine displacing 0.75 cu ft per rev at a pressure of 1 lb will have a slip of from 60 to 70 rev, while a machine having a capacity of 300 cu ft per rev will have a slip of from 3 to 5 rev. For intermediate capacities, the slip will vary proportionally and increase with higher pressures as the square root of the discharge pressure, *i.e.*, at 4 lb pressure the slip will be approximately twice that at 1 lb.

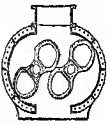

FIG. 3.—Roots Blower.

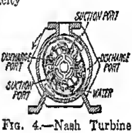

FIG. 4.—Nash Turbine Vacuum Pump.

Blowers of this type built by the Roots-Connersville Co. are suitable for capacities ranging from 5 to 10,000 cfm at pressures up to 5 to 10 lb per sq in. at speeds ranging from 250 for the larger sizes to 1,200 rpm for the smaller sizes. They are commonly used for cupola service, for sewage disposal plants, for low-pressure gas boosters in manufactured gas plants, and for blower service in general.

In most blower work, the so-called hydraulic formula for horsepower will be found satisfactory: hp $= Q(p_2 - p_1)/33{,}000$, where Q is the cu ft of air compressed per min, p_1 the initial pressure, and p_2 the final pressure, lb per sq ft. To get the actual horsepower at the shaft, the horsepower should be divided by the efficiency, which will vary from 0.80 to 0.90.

In the **liquid packing ring type** of blowers used for vacuum pumps or air compressors, water forms a seal between the suction and the discharge chambers. The turbine vacuum pump, shown in Fig. 4 (Nash Engineering Co., South Norwalk, Conn.), uses a bulged out casing and obtains two impulses in every revolution. A rotor revolves in an elliptical casing partly filled with water. The water approaches and recedes from the hub and in this manner acts as a liquid piston displacing the air in the spaces between the vanes of the impeller.

Starting at the point near the suction port, the chamber or space between the vanes is full of water. As the vanes rotate, the elliptical casing permits the water to be thrown out by centrifugal force and air is drawn in. After the inlet ports are passed, the water is forced back into the rotor by the elliptic casing, gradually compressing the air. When the rotor spaces

The mechanical efficiency of an air compressor is the work done in the air cylinders divided by the work done in the engine cylinders if driven direct by steam or gas engine, or by the work delivered at the belt if the compressor is belt driven.

Actual Values of Efficiencies. Tests of piston compressors show extreme variations of mechanical efficiency from 76 to 97 percent, with approximate averages for the more common sizes of 90 percent.

The volumetric efficiency of piston compressors varies from 50 to 75 percent for single-stage 100 lb machines to 80 to 90 percent for multistage machines in which the first-stage pressure does not exceed 30 lb per sq in. Where actual measurement of the air delivered by a compressor cannot be made, the volumetric efficiency may be very closely determined from the vacuum that can be developed by the compressor with the intake completely closed. The test to establish the vacuum developed with closed suction may be made by closing the intake of the compressor and allowing it to discharge into the atmosphere, or, if it is a multistage compressor, by allowing the first-stage cylinder to discharge into the atmosphere.

$$e = 1 - P_2(b - v)/P_a b$$

where e = volumetric efficiency, per cent; P_2 = absolute pressure under which compressor (or first stage) normally operates, lb per sq in. abs; P_a = normal suction pressure, lb per sq in. abs; v = vacuum developed on closed suction, in. of mercury; b = barometer, in. of mercury.

Average values of volumetric efficiency for single-stage compressors with various percentage clearances, taking into account leakage, heating, and other factors, are given in Fig. 22.

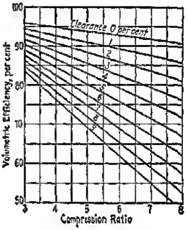

FIG. 22.—Volumetric Efficiency at Various Compression Ratios and for Various Percentages of Cylinder Clearance.

Compression efficiency varies with the number of compressions as well as all factors affecting volumetric efficiency, except clearance. Average or good values, calculated on an adiabatic base, are given below for atmospheric intake pressure.

Discharge air pressure, lb per sq in., gage	10	20	30	40	60	80	100
Compression efficiency (adiabatic base)	0.74	0.82	0.88	0.89	0.89	0.90	0.90

Horsepower Required to Compress a Gas (see p. 319). The horsepower required to compress a gas in a single-stage compressor is

$$\text{Hp} = \frac{144}{33{,}000}\frac{n}{n-1}p_1V_1\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}} - 1\right]$$

where V_1 represents the volume (cu ft) of gas compressed per minute and p_1 and p_2 the pressures lb per sq in. abs.

Values of $\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}}$ may be obtained from Table 16, p. 314. Since this tabulation is for expansion from p_1 to p_2, the values of p_1/p_2 of the tabulation are the same as p_2/p_1 in the preceding expression.

have reached the outlet ports the air has been compressed to the terminal pressure and is then discharged completely by the reentering water.

Liquid-packed ring-type rotary compressors are suitable for pressure ranges up to approximately 75 lb per sq in. and vacuum up to approximately

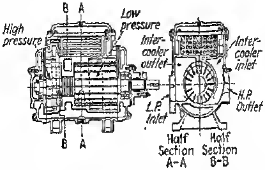

FIG. 5.—Two-stage Sliding-vane Compressor. (Allis-Chalmers "Ro-Twin.")

27 in. Hg in a single stage. Two-stage equipment is available for higher pressures. Standard sizes are available over a wide range of capacities. They are used to advantage where the air or gas to be compressed must be oil free, for example, in certain chemical processes or sewage disposal.

Sliding-vane rotary compressors, originally developed more than 25 years ago, have been used extensively in Europe and have been introduced in the United States by Yeomans Brothers Co., the Fuller Co., and the Allis-Chalmers Co. The principle of operation is shown diagrammatically in Fig. 5. Compressors of this type are built for discharge pressures up to 125 lb per sq in. in capacities up to about 2,000 cfm. Single-stage machines are generally used for pressures up to 50 lb per sq in. and two-stage machines for higher pressures. They are designed to operate at standard electric motor speeds ranging from 3,600 in the smaller sizes to 450 rpm in the larger sizes.

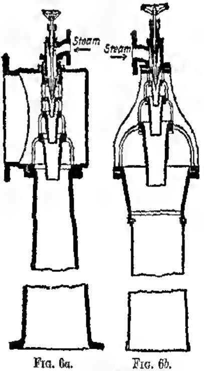

FIG. 6a. FIG. 6b.

FIG. 6a.—Körting Exhauster.

FIG. 6b.—Körting Steam-jet Air Compressor.

Steam-jet Blowers. Steam jets have long been used for "blowing" or exhausting in order to maintain combustion in locomotive boilers, usually employing the exhaust from the engines through properly shaped "nozzles." This type of air compressor or exhauster also finds extended application for emergency use and at times in permanent installations for removing foul air from mines, factories, ship holds, and for gas exhausters, for securing forced draft, and for handling gases under low pressures in certain

Representing the intercooler pressure by p_i, the work done in both cylinders of a two-stage compressor will be

$$\text{Hp} = \frac{144}{33{,}000}\frac{n}{n-1}p_1V_1\left[\left(\frac{p_i}{p_1}\right)^{\frac{n-1}{n}} + \left(\frac{p_2}{p_i}\right)^{\frac{n-1}{n}} - 2\right]$$

With perfect intercooling, $p_1V_1 = p_iV_i$. The preceding expression for the total work will be a minimum when $p_i = \sqrt{p_1p_2}$.

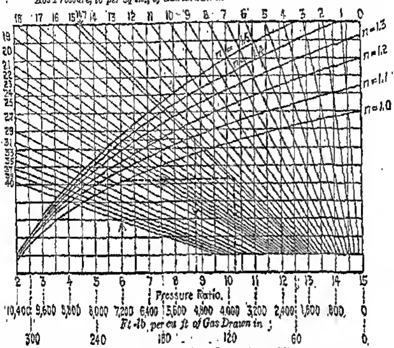

FIG. 23.—Chart for Determining the Work Done in Single-stage Gas Compression (Lucke).

The proper intercooler pressures for three-stage compression are

First intercooler, $p = \sqrt[3]{p_1^2p_2}$; second intercooler, $p = \sqrt[3]{p_1p_2^2}$

The minimum work done in compressing a gas is given by

$$\text{Hp} = 2 \times \frac{144}{33{,}000}\frac{n}{n-1}\cdot p_1V_1\cdot\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{2n}} - 1\right] \text{ for two-stage compressors}$$

$$\text{and hp} = 3\times\frac{144}{33{,}000}\frac{n}{n-1}\cdot p_1V_1\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{3n}} - 1\right] \text{ for three-stage compressors.}$$

With perfect intercooling, the volumes of the cylinders should be inversely as the pressures of the gas admitted to them.

Professor Lucke ("Engineering Thermodynamics") gives a number of charts for solving graphically many of the problems of gas compression, of which Fig. 23 is a very convenient one for determining the work per cubic foot and the horsepower per 1,000 cu ft of gas compressed in a single stage to any pressure up to 15 times its initial pressure and for various kinds of compression curves from the isothermal to the adiabatic.

chemical industries. Among its advantages are simplicity, ease of operation, small space, minimum of repairs, and ease of regulation.

Figure 6*a* shows a **Körting exhauster** for removing air, and Fig. 6*b* a Körting compressor of the steam-jet type. These machines are built in capacities of 10 to over 20,000 cfm and usually operate with steam at from 60 to 100 lb gage pressure. In some cases, they are operated by water under pressures from 1 to 45 lb gage. A. von Ihering ("Die Gebläse") reports some tests as to **steam consumption** which indicate 0.19 to 0.37 lb of steam required per 1,000 cu ft of air handled, the larger sizes being the more economical.

Steam-jet exhausters are used principally for lifting liquids as, for example, in creosoting plants, for forcing or inducing air or gases through liquids, for priming centrifugal pumps, etc. A typical performance is shown in the following table:

1 In. Steam Jet Primer
(Steam-operated air exhauster, cubic feet of free air per minute)

Steam pressure, lb per sq in. gage	Vacuum, in. of mercury (barom 30 in.)						
	1¼	5	8	10	15	23	26
25	40	9	0				
50	40	17	12	9	4	0	
75	40	19	14	11	7	2	0
150	40	20	15	13	8	2	0

Water-jet exhausters are also used for priming and other purposes. Typical performance data for water under 70 ft head are given below. The second line gives the free air exhausted per 100 gal of water.

Vacuum in in. of mercury (barom 30 in.).....	4	5	7	10	15	20	25	30
Air in cu ft per 100 gal of water............	23	18	13	8.5	4.5	2.2	0.8	0

Hydraulic Compressors. Several devices have been made for utilizing falling water for the purpose of compressing air without the use of any mechanical moving parts. The most successful of these is the **Taylor compressor,** shown diagrammatically in Fig. 7. In the figure, air tubes are represented at C, all terminating at the conical entrance B to the downflow pipe E. The water supply is furnished through the flume D. As the water falls, it draws air through the small tubes, carrying it down to the separating tank G, where it is liberated at a pressure depending on the weight of water in the vertical pipe H. The compressed air is then conducted through the pipe K to the place where it is to be used. The vertical distance from M to the tail race L represents the fall of water that is available.

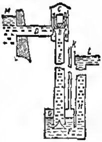

Fig. 7.—Taylor Hydraulic Air Compressor.

In this system, the compression is isothermal and the compressed air is saturated with moisture. The oxygen content of the air is reduced, which renders the air less beneficial for purposes of mine ventilation if the exhaust from the air tools is planned to assist ventilation. The system offers a very simple solution for utilizing water powers when the market for compressed air justifies its installation. It has the advantage of simplicity with a minimum of operating expense, and very high efficiencies are secured. The first cost of the installation is likely to be high.

In Fig. 23 the diagonal lines represent various absolute pressures for the gas drawn in, and the curved lines apply to various kinds of compression curves. The lower horizontal scale gives pressure ratios, work, and horsepower. In using the curves, follow vertically from the pressure ratio to the n curve, horizontally to the inlet pressure line, and vertically downward to the horizontal axis where the work and horsepower may be read. For example, if the compression ratio is 6, the compression curve follows the equation $p_1V_1^{1.4} = p_2V_2^{1.4}$, and the gas is at 14.7 lb per sq in. abs; there will be required 4,960 ft-lb of work per cu ft of gas compressed, or 152 hp per 1,000 cu ft of gas per min.

If the compression for the same pressure range (or to 88.2 lb per sq in. abs) had followed the isothermal compression curve, it would have required 3,880 ft-lb of work per cu ft, or 120 hp per 1,000 cfm.

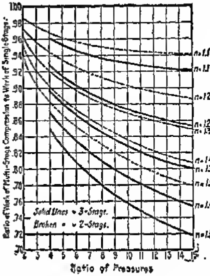

Fig. 24.—Chart for Determining the Work Done in Two- and Three-stage Gas Compression (Lucke).

Figure 24 enables calculations to be made for work and horsepower for two- and three-stage compression, when used in connection with Fig. 23. The dotted lines represent two-stage and the full lines three-stage compression and are marked according to the character of the compression curve. The horizontal scale shows pressure ratios and the vertical scale ratio of work or horsepower for two- or three-stage compression to the work that would be required for single-stage compression as determined from Fig. 23. For example, for a pressure ratio of 8, or a discharge of 117.6 lb per sq in. abs on a suction pressure of 14.7 lb, the work for a compression following the equation $p_1V_1^{1.4} = p_2V_2^{1.4}$ would be 85.2 percent of the work for the same conditions single-stage if two-stage were used and 81 percent of it if three-stage compression were used.

Effect of Altitude. As the density of the atmosphere decreases with the altitude, a compressor located at a high altitude will take in a smaller weight of air at each stroke. The reduction of pressure at the inlet affects the power expended in compressing the air, but the decrease in power required does not vary in the same ratio as the decrease in capacity. For this reason, compressors to be used at high altitudes should have the steam and air cylinders properly proportioned to meet the varying conditions at different levels. Table 5 shows the variation in capacity and horsepower for various altitudes. The altitudes given are heights above mean sea level and are subject to correction for temperature and latitude. From the table, it can be seen that for a two-stage compressor discharging at 100 lb pressure when operating at an altitude of 8,000 ft the weight of air compressed will be only 76 percent of that at sea level and the horsepower required will be 85 percent of that at sea level.

Figures 25 and 26 show the performance of typical single- and two-stage compressors, respectively, when operating at sea level and different altitudes

In 1906, a large plant of this type was installed at the Victoria Copper Mine, near Rockland, Mich., consisting of three units with a total capacity of 34,000 to 36,000 cu ft of free air per minute. A series of tests made on a single intake head by Prof. F. W. Sperr gave the results shown below.

Air measurements				Water measurements			
Free air, cu ft per min	Abs pressure, lb per sq in.		Horse power	Cu ft per min	Head, ft	Horse power	Efficiency, percent
	Free air	Compressed air					
10,580	14	128	1,430	13,057	70.5	1,741	82.17
11,930	14	128	1,623	14,820	70.0	1,961	82.27
9,238	14	128	1,248	12,710	70.6	1,700	73.50

Figure 8 illustrates some of the dimensions of a Taylor hydraulic compressor installed near Cobalt, Ontario, Canada. This was designed for a capacity of 40,000 cu ft of free air per minute to be compressed to a gage pressure of 120 lb. The compressed air is conducted to mines through 9 miles of 20 in. pipe leading to two 12 in. lines with a total distributing line of 21 miles in length. The

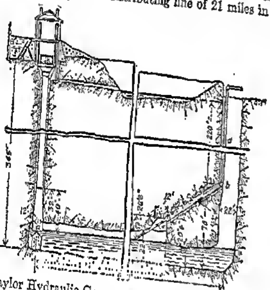

FIG. 8.—Taylor Hydraulic Compressor Installation near Cobalt, Ont.

water is admitted through suitable gates to two "heads" each 16 ft diam and containing 66 pipes each 14 in. diam. The size of the heads is reduced in diameter to about 8 ft, and the whole apparatus can be raised or lowered as required by operating conditions. A cone *a* assists in separating the air and water, and the long horizontal tunnel permits quite complete separation. The compressed air is removed through the pipe *c* and the water freed from the entrained air escapes through the vertical shaft *b*. Pipe *e* acts as a relief for a surplus of compressed air. Its end is normally below the surface of the water in the tunnel, but if the amount of air should accumulate it would be exposed and permit the escape of the surplus air without seriously affecting the normal air pressure of the distribution system.

Piston Compressors and Blowers

For pressures ranging from 5 lb per sq in. to the maximum workable pressure, compressors of the reciprocating piston type are most commonly

for various discharge pressures. Volumetric efficiency shown on the charts is defined on p. 1646 and should not be confused with the quantity coefficient tabulated in Table 5.

Table 5. Variation with Altitude of Quantity and Horsepower Coefficients for Two-stage Air Compression

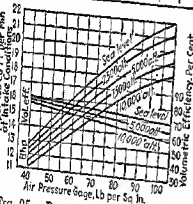

Fig. 25.—Representative Single-stage Compressor Performance.

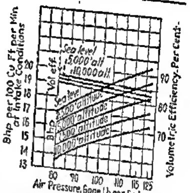

Fig. 26.—Representative Two-stage Compressor Performance.

REGULATION, REHEATING, LUBRICATION

Unloading Devices. Many compressors operate at constant speed, independent of the demands for compressed air; and, in order to secure economy of operation for this condition, various types of "unloaders" have been designed. For small single-stage compressors, some builders provide an unloading valve connected by piping to the inlet valves. When the predetermined pressure is exceeded, the unloader raises the inlet valves from their seats and prevents further compression of air until the pressure falls a few pounds, when the unloader allows the valves to resume their seats and the work of compression is again taken up. An inlet valve so equipped is shown in Fig. 27. Other manufacturers use a similar device to keep the

used. For the lower pressures, compression is generally accomplished in a single stage. For large size cylinders (300 to 5,000 cfm), the limit of pressure per stage is generally set at not more than 3 to 4 compressions; for relatively small sizes (50 to 300 cfm) the limit may be as high as 7 or 8 compressions, and for very small capacities (1 to 50 cfm) 15 compressions is not uncommon.

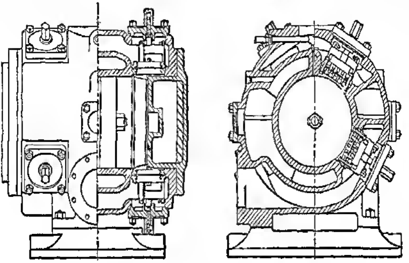

FIG. 9.—Double-acting Air Compressor with Feather Valves.

When the total pressure does not exceed 500 to 600 lb per sq in., cylinders of the double-acting type are generally used. A typical design is that shown in Fig. 9, which illustrates a Worthington feather-valve cylinder of moderate size. For very high pressure, particularly for the third and fourth stage of multistage compressors, cylinders of the single-acting plunger type give the

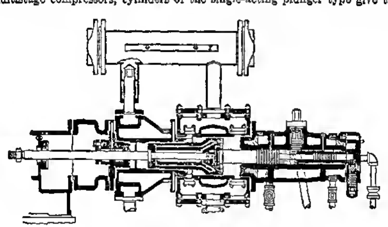

FIG. 10.—Four-stage 4000 lb Compressor.

best service. The plungers may be either ring-packed or packed with soft or semipliable metallic packing using gland and stuffing-box construction. Figure 10 shows a four-stage 4,000 lb compressor. Compressor cylinders and cylinder heads should be as completely jacketed as possible. The air ports and passages are generally proportioned to limit the average air velocity through them to not more than 2,000 fpm. For compressors having a piston

inlet closed when the predetermined pressure is reached. For larger compressors, a *double-beat valve* is used, which is placed on the air-inlet duct and controlled by air pressure from the air receiver. This valve is set to shut off completely all the incoming air when the receiver pressure rises above a predetermined point. In order to relieve the high-pressure cylinder during intervals of unloading, high-pressure relief valves are used.

A total-closure suction unloader is shown in Fig. 28. The discharge pressure acting on the piston *A* compresses the spring *B*; when the port *C* is uncovered, the air has access to the under side of the valve *D* and closes it.

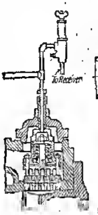

FIG. 27.—Unloading Inlet Valve.

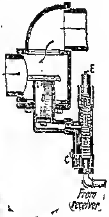

FIG. 28.—Suction Unloader.

Another widely used type of compressor regulation is the variable clearance control. The compressor cylinder (Fig. 29) is equipped with clearance valves *A*, *B*, *C*, and *D*. These valves open communication between the cylinder and the clearance pockets *E*, *E*. The clearance valves are piped to a regulator controlled by the air pressure.

A third type of compressor for variable volume at constant speed is shown in Fig. 30. In this a combination of clearance and suction-valve by-pass control

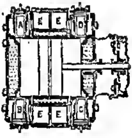

FIG. 29.—Variable Clearance Compressor.

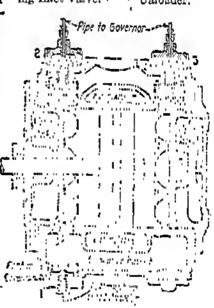

FIG. 30.

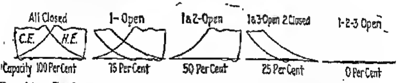

FIG. 31.—Cards from Compressor with Combination Clearance and Suction-Valve By-pass Control.

is employed. The first step of unloading is effected by means of a clearance pocket on one end of the cylinder, the second by holding open the suction valves on the same end, the third by holding open the suction valves on the other end and permitting the first

speed of not more than 700 fpm, the intake pipe connection varies in diameter from $\frac{3}{8}$ to $\frac{1}{2}$ of the cylinder diameter and the discharge connection from $\frac{1}{3}$ to $\frac{1}{2}$ of the cylinder diameter.

Piston speeds, commonly used for air and gas compressors, have been greatly increased since the practical elimination of the mechanically operated valve and the introduction of modern lightweight plate and strip valves. Although some compressors are now built for piston speeds as high as 830 fpm, it is considered better practice to limit speeds to 650 to 750 fpm, with the lower limit for smaller units and the higher limit for larger units. Rotative speeds are fixed to correspond to these piston speeds and vary from 800 for 6 in. stroke compressors to 150 rpm for 30 in. stroke compressors.

The large quantities of air required for blast furnaces and Bessemer converters were, until recently, usually supplied by piston compressors of large capacity, driven either by steam or gas engines. The turboblower directly driven by steam turbines or electric motors has supplemented almost completely the reciprocating piston blowing tubs for this service.

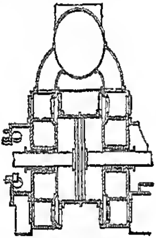

FIG. 11.—Blowing Tub.

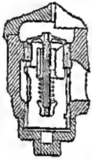

FIG. 12. Inlet Valve.

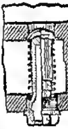

FIG. 13. Discharge Valve.

Ingersoll-Rand.

Piston compressors used as blowers for blast furnaces and Bessemer converters usually operate at discharge pressures of 15 or 20 lb gage with piston speeds as high as 800 fpm. In order to provide sufficient valve area, it is necessary to increase cylinder clearance to $9\frac{1}{2}$ to $11\frac{1}{2}$ percent of the piston displacement. Figure 11 shows the head and valve arrangement of a typical small-sized blowing tub.

Compressor valves are generally of the automatic type as distinguished from the mechanically actuated type. For small compressors, or the high-pressure stages in high-pressure compressors, poppet valves of the single-beat cup type are most extensively used (Figs. 12 and 13). For all other services, some one of the various lightweight plate or strip valves are used. Plate valves may be classified into three groups: (1) rigidly attached disk valves with integrally connected rings and spring element, (2) semi-attached strip or ribbon valves, (3) unattached and independent plate valves. The Ingersoll, the Worthington Feather Valve, and the Chicago Pneumatic Simplate are typical examples of valves falling in the three preceding classifications.

In the **Ingersoll valve** (Fig. 14), the valve disk is made from a thin sheet of steel. The outer portions of this disk are used as valve rings, and the inner portion is used to give the disk elasticity and to guide it. The valve

suction valves to function, and the last step or complete unloading is effected by holding open all suction valves, completely by-passing all air entering the cylinder. Typical indicator cards are shown in Fig. 31.

The performance of a 15½ and 9¾ × 10 direct-connected compressor equipped with combination clearance and by-pass volume control and operated at 360 rpm against 100 lb gage discharge pressure with atmospheric intake at sea level is as follows:

Item	Full load	¾ load	½ load
Displacement, cfm	782.		
Volumetric efficiency, percent	84.1		
Actual capacity, cfm	664.	498.	332.
Total bhp	126.7	98.5	71.5
Bhp per 100 cfm	19.10	19.78	21.5
Total electrical hp	135.	105.	77.
Electrical hp per 100 cfm	20.3	21.1	23.2

Regulators. **Variable capacity control** is obtained in various ways. One method uses solenoid-operated three-way valves to control the admission of air pressure to the compressor unloading elements. The solenoids, mounted on the compressor, are arranged to unload when deenergized and, therefore, may be electrically interlocked with a motor starter for **automatic initial unloading.** The electric circuit to each solenoid is completed through a governor instrument which may be mounted remotely from the compressor.

A **combined speed and pressure** governor (Ingersoll-Rand) for steam-driven compressors is illustrated in Fig. 32. It is of the hydraulic type, operated by means of a small oil pump *A* driven from the compressor shaft. Raising or lowering of the rack and weight *B*, which is a part of the governor, controls the cutoff position of the steam valves and varies the speed of the compressor. Movement of the weight is accomplished by a change in the pressure of the oil under the plunger. The pressure variation is a resultant of the simultaneous action of two separate methods of regulation. Pump *A*, which is chain driven from the main shaft, produces a flow of oil under pressure acting against the governor plunger. Variation in steam pressure produces a change in the oil pressure and causes a movement of the weight and rack and changes the cutoff in such a way as to restore the required speed. Variation in the demand for air or gas also affects this oil pressure by means of a diaphragm-operated valve *D* which by-passes a portion of the flow of oil. The diaphragm is connected to receiver pressure.

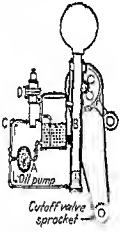

Fig. 32.—Combined Pressure and Speed Governor. (Ingersoll-Rand.)

Water Jackets, Intercoolers, Receivers, and Aftercoolers. In good modern practice, the number of square feet of cooling surface per 100 cu ft of free air per minute with brass tubes and for compression to 80 to 125 lb gage is about as follows:

Cooling water temp., F	60	70	80	90
Cooling surface, single-stage, sq ft	16	17	20	23
Cooling surface, two-stage, sq ft	13	13	14	15

is held rigidly through the elastic central portion. The spring loading of the valve is effected by means of spring elements forming part of the cushion plate. The lift of the valve does not exceed ⅛ in. In the **Ingersoll channel valve**, two or more parallel valve members, shaped like a channel, lift uniformly from their seat for their entire length. The back of the channel forms the seat, against which it is held by a flat ribbon spring, bowed against the valve guard at the middle and against the channel at the two ends. The flat spring is the width of the channel opening, which forms the spring retainer. The valve channel is retained in position by recesses in the guard at the ends. The lift of the valve is approximately ⅛ in. The **Worthington feather valve** is shown in Fig. 15. The valve proper is made up of a series of thin flexible strips of ribbon steel, held in position over rectangular openings in the seat by curved milled guards in the valve cover. The valve strips have a lift of about ⅛ in. at the middle and about ⅛ in. at the ends, giving large lift areas. Ribbon steel springs are placed over each valve strip, bowed against the guard at the middle and against the valve strip at the ends. In opening, the spring allows the strip to lift uniformly for half its lift and then flex against the curved guard for the rest of its travel. The **Chicago pneumatic simplate valve** is shown in Fig. 16. The valve seat has circular ports over which are placed, concentrically, thin ring valve elements. These are held down by means of a number of small helical springs. The lift of the outer or larger rings is generally not more than ⅛ in., and that of the inner or smaller rings is sometimes made somewhat less.

Seat Valves Cover

FIG. 15.—Worthington Feather Valve.

Seat Valves Cover

FIG. 16.—Simplate Compressor Valve.

The area through the valves for any compressor depends upon the piston speed and also on the rotative speeds. In some designs, the area through the intake valves is made larger than that through the discharge valves. Generally, however, it is made the same. In low-pressure compressors, or blowing tubs, the valve area is made large enough to give an average velocity of 3,500 to 4,000 fpm. For higher pressures (30 lb per sq in. and over), 5,000 fpm is considered satisfactory. For high rotative speeds and relative low piston speeds, the limits given above may be somewhat exceeded, and for low rotative speeds and high piston speeds they represent the limit of good practice.

Vacuum Pumps. A vacuum pump is essentially a compressor. It takes its suction at low absolute pressure, compresses through a large number of compressions, and generally discharges to the atmosphere. For condenser service, a vacuum pump must develop a vacuum varying from 27 to 29½ in. of mercury. For other services, for example pumping gas out of oil wells, vacuums from 15 to 28 in. of mercury are common. Vacuum pumps for

The number of gallons of cooling water required for aftercoolers (A), intercoolers (I), and cylinder jackets (J), per 100 cu ft of free air compressed, is given by The Compressed Air Society as follows:

Apparatus	No. of stages	Compression pressure, lb gage	Water temperature, F			
			60	70	80	90
A or I	2	80–100	2.5	3.0	3.5	4.0
I and J	2	80–100	2.9	3.4	4.0	4.5
A	1	80–100	4.0	4.5	5.2	6.0
J	2	80–100	0.85	1.0	1.2	1.4
J	1	40	0.5	0.6	0.7	0.9
J	1	60	0.6	0.7	0.8	1.0
J	1	80	0.7	0.8	0.9	1.1
J	1	100	0.8	0.9	1.0	1.2

Receivers are used to supply a reservoir of air, to equalize the pulsations in the air coming from the compressor, to collect the water and grease held in suspension by the compressed air as it leaves the compressor, to reduce the friction of air in the pipe system, and to cool the air as thoroughly as possible before entering the transmission system. To facilitate the removal of water from the compressed air, an **aftercooler** is frequently used. It precipitates the water and thus reduces difficulties in transmission lines and tools. When the transmission pipe line is long, receivers should be placed at both ends of the pipe.

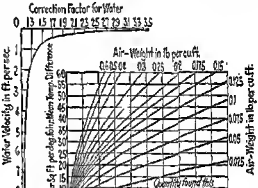

Fig. 33.—Heat Transfer Rate for Aftercooler. (Schutte and Koerting Co.)

Figure 33 gives the heat transfer in Btu per hr per sq ft of surface per deg F mean temperature difference between the air and water with different air velocities in fps for aftercoolers. Thus for an air velocity of 50 fps and for an air density of 0.2 lb per cu ft, the heat transfer rate is about 48. This value, however, must be corrected for the velocity of the water. On the assumption that the latter is 1 fps, the correction factor from the curve is 1.4. The corrected heat transfer rate is $48/1.4 = 34$ Btu.

Reheaters. Heating the air just before expansion may increase the efficiency of the system and, in addition, will increase the temperature at the end of expansion and prevent the freezing up of the motor.

In quarry work, **stoves** are sometimes used for preheating the air. In locomotive work for mines and surface use, hot water is frequently employed for this purpose.

Reheaters are usually capable of raising the temperature of the air to from 300 to 500 F, although common practice shows temperatures of 250 to 350. In figuring on reheaters, it is usual to assume that 1 lb. of coal will

high vacuum are either of the close-clearance type or of the flash-port type. An example of the latter developed by Wheeler is shown in Fig. 17. One suction valve is used which turns alternately to admit air to one end of the cylinder and then to the other. A flash port, cored in the suction valve, opens communication between the clearance space of one end of the cylinder and the compression of the other end, just as the suction and discharge passages are closed. A row of poppet valves controls the discharge. The close-clearance type of pump is identical in construction with that of any air compressor. The valves, usually of the plate or strip type, are placed in the cylinder heads in order to reduce clearance to a minimum. For high vacuum, two-stage pumps are most commonly used. Figure 18 shows a single-cylinder two-stage vacuum pump developed by the Worthington Corp., in which the air is first taken into one end of the cylinder and then discharged directly into the other end of the cylinder, which has a large clearance volume, where it is compressed and discharged into the atmosphere. Pumps of this type develop a vacuum, on closed suction, equivalent to a pressure of less than 0.1 in. of mercury absolute.

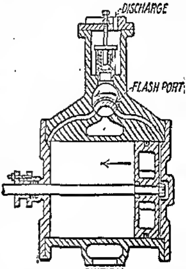

FIG. 17.—Wheeler Flash-port Vacuum Pump.

The capacity of single-stage vacuum pumps, or the volumetric efficiency, may be very approximately measured by the vacuum developed with the intake completely closed. $Q = D(V - V_w)/B$, where Q is capacity, cfm; D the displacement; V the vacuum developed on closed suction; V_w the working vacuum; and B the barometric pressure, all in in. of mercury. The air-handling capacity of vacuum pumps on condenser service must be calculated not from the observed vacuum but from the partial pressure of the air taking into account the vapor pressure of the steam entering the cylinder with the air.

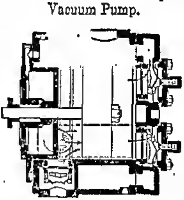

FIG. 18.—Single-cylinder Two-stage Vacuum Pump.

Injection compressors for Diesel engines may be either two or three stage; the latter, however, is preferable. In order to regulate the capacity, one of three methods is generally used: (1) throttle valve in the compressor intake, (2) bleeder valve from the first stage discharge, (3) clearance pockets in the low-pressure cylinders with valves for opening or closing them as occasion demands.

AIR COMPRESSION

For the theory of air compression, see p. 319.

Mean Effective Pressure in Multistage Compression. The mean effective pressure, with complete intercooling, referred to the low pressure piston, is expressed by the formula

$$p_m = p_1\left\{\frac{Nn}{n-1}\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{Nn}} - 1\right]\right\}$$

give from 8,000 to 10,000 Btu to the air. As the specific heat of air is approximately 0.24, 1 lb of coal will raise the temperature of approximately 100 lb (or 1,200 cu ft) of free air 300 deg.

The increase in efficiency resulting from reheating is greater with tools that use air expansively than with machines taking in air for full stroke. Sometimes it is not desirable to have the air entering a tool at a temperature above 300 F because of the effect of this high temperature on the lubrication. For these conditions, small portable hot-water stove-type reheaters are available in capacities of 62 to 800 cu ft of air per min.

Lubrication (See p. 1902). If oil is fed too rapidly in the air cylinders or if it is of unsuitable quality, there is a gradual accumulation of carbon, which interferes with the free movement of the valves and may actually choke the passages and produce high temperatures sufficient to produce ignition or **explosion.**

Explosions have taken place from the introduction of kerosine or naphtha into the air cylinder for the purpose of cleaning the valves and cutting away the carbon deposits. This is a very effective way of **cleaning valves and pipes,** but is a source of danger and should be absolutely prohibited.

In order to reduce the danger of excessive temperatures, fusible **safety alarm plugs** may be inserted in the discharge line. These are usually set for a temperature of 350 F for a single-stage compressor working at 40 lb gage pressure, for a two-stage compressor at 100 lb gage, and for a three- or four-stage compressor delivering at 1,000 lb gage. A 500 F plug is furnished for use with a single-stage compressor discharging at 100 lb gage pressure.

where N represents the number of stages and n is the exponent of the compression curve. Figure 19, from a chart plotted by F. W. O'Neill, shows the relation between the mean effective pressure and the initial pressure for various pressure ratios p_2/p_1 with adiabatic compression and complete intercooling. For isothermal compression, $p_m = p_1 \log_e (p_2/p_1)$.

Wet vs. Dry Compression. The ideal method of compressing air when it is to be stored or allowed to cool before being used is the isothermal, and in the earlier types of compressors this was attempted by so-called wet compressors, by means of which it was possible to secure compressions approximating $p_1V_1^{1.2} = p_2V_2^{1.2}$. The mechanical difficulties involved and the necessary low speeds with consequent small capacity have led to the use of modern "dry compressors," which in small sizes have cylinders with cast-iron ribs for radiating heat and in large sizes have water jackets surrounding the cylinder. The cooling thus secured is sufficient to keep temperatures from being excessive, but as a rule the compression curves are above $pV^{1.35}$ = constant. Dry compression has the advantage of higher speeds and larger capacities.

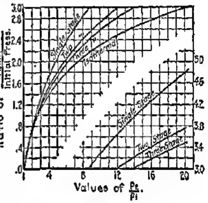

Fig. 19.—Mean Effective Pressures in Air Compression.

Efficiencies. The **volumetric efficiency** of an air or gas compressor is the ratio of free air at intake pressure and temperature actually drawn in, to the piston displacement. The principal sources of volumetric loss are wiredrawing, heating of the air during admission to the cylinder, leakage past valves and pistons, and reexpansion of the clearance air. Except for the last item, none of these losses can be directly measured, so that a determination of volumetric efficiency involves the actual measurement of the air delivered. The low-pressure orifice is generally used for this purpose (see A.S.M.E. Power Test Code for Compressors). Figure 20 shows a typical compressor card. The clearance loss is proportional to MK. If the clearance expansion line follows the equation $p_JV_J^n = p_KV_K^n$, where the clearance $C = V_J/L$, then $V_K/L = (p_J/p_K)^{\frac{1}{n}}C$. The volumetric loss due to clearance may also be written

Fig. 20.—Air Compressor Card.

$$\frac{V_K - V_J}{L} = C\left[\left(\frac{p_J}{p_K}\right)^{\frac{1}{n}} - 1\right]$$

Example. If p_J is 94.7 lb per sq in. abs and C is 2 percent, the volumetric loss due to clearance will be $0.02\left[\left(\frac{94.7}{14.7}\right)^{\frac{1}{1.4}} - 1\right] = 0.0556$.

CENTRIFUGAL COMPRESSORS

BY

JOHN AVERY

From "Mechanical Engineers' Handbook," edited by Lionel S. Marks

REFERENCES: Eck-Kearton, "Turbo-Gebläse und -Kompressoren," Springer. Kearton, "Turbo-blowers and Compressors," Pitman. Ostertag, "Kolben und Turbokompressoren," Springer. Zerkowitz, "Thermodynamik der Turbomaschinen," Oldenbourg. McBride, "Centrifugal Compressors," *Gen. Elec. Rev.*, May, 1932. A.S.M.E. Test Code for Centrifugal Compressors, Exhausters and Fans, Part I.

Centrifugal compressors are similar in design and construction to centrifugal pumps. The pressure that can be produced depends on the peripheral speed of the impeller wheel, the density of the fluid handled, the type of impeller blading used, and the number of wheels. Since air and other gases are relatively light, the centrifugal compressor must run at high speed. The compressibility of gases introduces a phenomenon, not present in centrifugal pumps, known as "pumping," or "surging," which occurs at low load.

Advantages. The high speed of centrifugal compressors makes them especially suitable for drive by steam turbines or electric motors. They can generally be direct-connected to their drives, but in some cases speed-increasing gears must be employed, particularly when the volumes to be handled are relatively small.

Centrifugal compressors for pressures below 1 lb per sq in. are generally known as *blowers* or *fans*. In these machines, the kinetic energy of the gas at the impeller exit is usually allowed to dissipate itself in eddies. For pressures greater than 1 lb per sq in., the kinetic energy is normally recovered as pressure by means of a diffuser. For air pressures of 6 lb per sq in. and under, a single impeller is generally sufficient. Higher pressures generally require two or more impellers in series. More than one impeller may also be required for pressures under 6 lb if the gas handled is lighter than air. Multi-stage compressors for pressures up to 30 to 35 lb gage are generally uncooled. For higher pressures, they are provided with special means for cooling the gas during its passage from stage to stage.

The centrifugal compressor is characterized by small dimensions, relatively light weight, and freedom from vibrations. The only rubbing parts are the bearings. The internal clearances between the rotor and the stationary parts are generally quite large. The air or gas is delivered in a steady stream, free of pulsations. No oil enters the air or gas stream, a desirable feature in many cases, particularly for chemical plants.

The centrifugal compressor is very flexible and easy to regulate, responding rapidly to changes in demand and lending itself readily to such forms of regulation as constant volume, constant suction pressure, and constant discharge pressure.

Limitations. Although a centrifugal compressor will maintain a fairly constant pressure over a wide range of quantities, there is, for every speed, a certain quantity below which the operation will be unstable. This *breakdown point* or *pumping limit* can be pushed back toward lighter loads by making the discharge vanes very few and their inlet angle small or by omitting them entirely. Also, when working on that part of the pressure curve where the pressure remains constant or increases with the quantity, there are usually pressure surges or pulsations which, although slight in themselves, may be greatly intensified by a sort of resonance effect if the volume of the inlet and discharge piping happens to have a certain critical value. A slight throttling

To Construct a Tangent at any given point P of a hyperbola. In Fig. 58, draw PA and PB parallel to the asymptotes, and take $OS = 2(OA)$ and $OT = 2(OB)$. Then ST is the tangent at P.

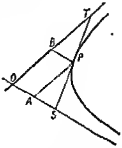

Fig. 58.

To Construct a Hyperbola, given the asymptotes and any point P

(1) In Fig. 59 let TPT' be a variable line through P, and lay off $T'P' = TP$; then P' is a point of the curve.

(2) In Fig. 60, draw PA and PB parallel to the asymptotes. Lay off $OA' = n(OA)$ and $OB' = (1/n)(OB)$, where n is any number; and through A' and B' draw parallels to the axes; these will meet in a point P' of the curve.

Fig. 59.

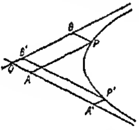

Fig. 60.

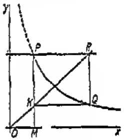

Fig. 61.

(3) (Fig. 61.) Take any point K in the ordinate PM, and draw OK meeting the line through P parallel to the x-axis in R. Draw a parallel to the x-axis through K and a parallel to the y-axis through R, meeting in Q. Then Q is a point of the curve.

THE CATENARY

The catenary is the curve in which a flexible chain or cord of uniform density will hang when supported by the two ends. Let w = weight of the chain per unit length; T = the tension at any point P; and T_h, T_v = the horizontal and vertical components of T. The horizontal component T_h is the same at all points of the curve.

The length $a = T_h/w$ is called **the parameter** of the catenary, or the distance from the lowest point O to the directrix DQ (Fig. 62). When a is very large, the curve is very flat. For methods of finding a in any given case, see problems 1–6 below.

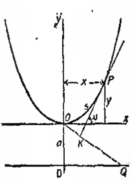

Fig. 62.

The rectangular equation, referred to the lowest point as origin, is $y = a\ [\cosh\ (x/a) - 1]$. (For table of hyperbolic functions, see p. 60.) In case of

very flat arcs (a large), $y = \frac{x^2}{2a} + \ldots$; $s = x + \frac{1}{6}\frac{x^3}{a^2} + \ldots$, approximately, so that in such a case the catenary closely resembles a parabola.

If the perpendicular from O to the tangent at P meets the directrix in Q, then $DQ = \text{arc } OP = s$ and $OQ = y + a$. The radius of curvature at P is $R = (y + a)^2/a$, which is equal in length to the portion of the normal intercepted between P and the directrix.

Problems on the Catenary (Fig. 62). When any two of the four quantities x, y, s, T/w are known, the remaining two, and also the parameter a, can be found, as follows:

(1) GIVEN x AND y. Compute y/x, and find from Table 1 the value of the auxiliary variable z. Then compute $a = x/z$, $s = a \sinh z$, and $T = wa \cosh z$. Or, having z, find s/x and wx/T by using Tables 3 and 2 inversely, and hence (since x is known) compute s and T/w without the use of a.

TABLE 1. GIVING z WHEN y/x IS KNOWN. THEN $a = x/z$

y/x	0	1	2	3	4	5	6	7	8	9

NOTE. $wx/T = z/\cosh z$. If wx/T is less than 0.6627, there are two values of z, one less than 1.200 and one greater than 1.200; *only the smaller of these values is tabulated.* If wx/T is greater than 0.6627, the problem is impossible.

(3) GIVEN x AND s. Compute s/x, and find from Table 3 the value of the auxiliary variable z. Then compute $a = x/z$, $y = a(\cosh z - 1)$, and $T = wa \cosh z$. Or, having z, find y/x and wx/T by using Tables 1 and 2 inversely, and hence (since x is known) compute y and T/w without the use of a.

of the inlet will always stop these pulsations by making the pressure curve slightly drooping.

Theory. The theory of the centrifugal compressor follows closely the theory of the centrifugal pump, the main differences being due to the compressibility of gas.

A rapidly rotating impeller wheel (Fig. 1) draws in the gas at its center, or eye, and discharges it at high velocity into an annular diffuser. The diffuser reduces the velocity of the gas and converts its kinetic energy into pressure.

The impeller wheel may take one of several forms. The most commonly employed forms are the **backward bladed**, in which the blades curve or slope away from the direction of rotation, and the **radial bladed**, in which the blades are straight and extend radially. In some few cases, a combination of the two types is used. Each type has features of advantage for specific conditions. In general, the radial-bladed wheel produces a higher pressure for a given peripheral speed and may be operated at higher speeds than the backward-bladed wheel. On the other hand, the backward-bladed wheel gives a somewhat steeper pressure-volume characteristic, has a lower *pumping* limit, and possesses a non-overloading power-input characteristic which is of particular value with motor-driven units.

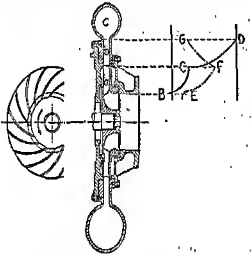

FIG. 1.—Single-stage Centrifugal Compressor with Backward-bladed Impeller *a*, Unbladed Diffuser *b*, and Spiral Volute *c* (*E-F-G* = Velocity Variation; *B-C-D* = Pressure Variation).

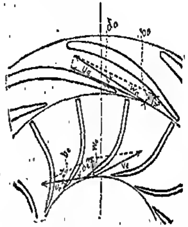

FIG. 2.—Velocity Diagram of Radial-bladed Impeller with Bladed Diffuser.

Figure 1 shows a typical single-stage centrifugal compressor with backward-bladed wheel, illustrating the distribution of velocity and pressure in the wheel and diffuser. Figure 2 shows a radial-bladed wheel in combination with a bladed diffuser.

Notation. Referring to Fig. 2, let

$D_e(D_a)$ = impeller inlet (exit) diameter, ft

$u_e(u_a)$ = impeller inlet (exit) peripheral velocity, ft per sec

$w_e(w_a)$ = absolute inlet (exit) velocity of gas, ft per sec

$v_e(v_a)$ = relative inlet (exit) velocity of gas, ft per sec

$b_e(b_a)$ = impeller inlet (exit) angle, deg

d_e = angle between w_e and u_e, deg

during compression, either by means of water jackets or intercoolers. They are especially suitable for plants where steam is available, enabling them to be direct-connected to steam turbines. Six to eleven stages are commonly employed (Fig. 9).

Centrifugal Compressor Applications

Among applications of interest to Marine Engineers are the following:

Refrigeration Compressors. Centrifugal compressors are used for mechanical refrigeration units in large capacities handling ammonia, methylene chloride, ethyl chloride, Freon 11, and water vapor.

They have found greatest application in connection with water-cooling systems for air-conditioning work. For this service, either Freon 11 or water vapor is generally used in this country. As a consequence of the high density of Freon 11 (the weight is about 4.5 times the weight of air) and the low ratio of specific heats, large pressure ratios can be produced in a few stages. For most water-cooling applications, two or three stages are sufficient. The design of such compressors involves special methods of preventing leakage of refrigerant and air infiltration.

Internal-Combustion Engines. Centrifugal compressors are used to supply scavenging air to large two-stroke Diesel engines. For this service, pressures from 1.75 to 3 lb gage are required for conventional stationary engines and higher pressures—up to 5 or 6 lb—for high-speed marine or traction engines. Single-stage compressors driven by electric motors are usual, although in some cases centrifugal compressors have been geared to the engine shaft. For supercharging gasoline and Diesel engines, centrifugal compressors driven by exhaust gas turbines are quite commonly used.

d_a = angle between w_a and u_a, deg, or inlet angle of discharge vanes, if any
p_1 = initial pressure of the gas, including the velocity energy (if any), lb per sq in.
T_1 = temperature of gas corresponding to p_1, deg F abs
d_1 = density of gas corresponding to p_1, lb per cu ft
p_2, T_2, d_2 = corresponding values for the final conditions of the gas as it leaves the compressor
k = ratio of specific heats of gas, taken as 1.395 for air
$Y = (T_2/T_1) - 1 = (p_2/p_1)^{(k-1)/k} - 1$; for air $= (p_2/p_1)^{0.283} - 1$
s = specific gravity of gas at inlet conditions, referred to that of "free air" as unity
Q = quantity of inlet gas, cu ft per sec
e_h = hydraulic efficiency, referred to adiabatic compression
H = the theoretical (or total) head, or height against which the gas is raised, ft, including all hydraulic losses
N = rpm.

For values of Y see Table 17, p. 315.

Total Pressure Rise. The fundamental equation giving the value of H is as follows:

$$H = (1/g)(u_a w_a \cos d_a - u_e w_e \cos d_e)$$
$$= (1/2g)(u_a^2 - u_e^2 + w_a^2 - w_e^2 + v_e^2 - v^2)$$

For single-stage compression,

$$Y = \left(\frac{p_2}{p_1}\right)^{(k-1)/k} - 1 = \frac{e_h d_1 (k-1) H}{144 p_1 k}. \quad \text{This is equal to } \frac{e_h d_1 (k-1) u_a^2}{4631 p_1 k}$$

when $d_e = 90$ deg (no inlet guide vanes) and $b_a = 90$ deg (radial discharge). Assuming $p_1 = 14.7$, $T_1 = 520$, $k = 1.395$, $e_h = 0.72$, and substituting, $p_2 = 14.7[1 + (u_a^2 s/4{,}300{,}000)]^{3.54}$. For small pressure rise, with $d_e = 90$ deg, $p_2 - p_1 = 0.0000165 e_h u_a^2 s[1 + (v_a/u_a) \cos b_a]$.

Fluid input horsepower is the horsepower applied to the gas and is independent of the actual pressure rise obtained. Fluid input hp $= Qd_1H/550$. For $d_e = 90$ deg, this becomes $0.00000432 Q s u_a^2 [1 + (v_a/u_a) \times \cos b_a]$.

Theoretical Horsepower. This is the horsepower necessary to compress (and deliver) Q cu ft of gas per sec from p_1 to p_2. When the compressor is not artifically cooled, it is common to refer its performance to theoretical **adiabatic horsepower.** The formula for theoretical adiabatic horsepower is

$$P_g = \frac{144k}{550(k-1)} p_1 Q \left[\left(\frac{p_2}{p_1}\right)^{(k-1)/k} - 1\right]$$

For normal air ($k = 1.395$), this formula becomes

$$P_g = 0.9252 p_1 Q[(p_2/p_1)^{0.283} - 1] = 0.9252 p_1 Q Y$$

Values of Y for air are given on p. 315. A more extensive tabulation is given in the A.S.M.E. Test Code for Centrifugal Compressors. Table 1 may be used for rough horsepower calculations, when the inlet pressure (p_1) is 14.7 lb abs. The figures given refer to an inlet volume of 100 cfm.

Table 1. Theoretical Adiabatic Horsepower

CENTRIFUGAL AND PROPELLER FANS

BY

H. F. HAGEN

From "Mechanical Engineers' Handbook," edited by Lionel S. Marks

REFERENCES: Innes, "The Fan," Technical Publishing Co. Lorenz, "Neue Theorie und Berechnung der Kreiselrader," Oldenbourg. Keller and Marks, "The Theory and Performance of Axial-flow Fans," McGraw-Hill. Spannhake, "Centrifugal Pumps, Turbines, and Propellers," The Technology Press, Cambridge, Mass.

Symbols: p = total pressure, in. of water, above barometric pressure
p_s = static pressure, in. of water, above barometric pressure
p_v = velocity pressure, in. of water
V = absolute velocity, fps
v = velocity of air relative to fan wheel, fps
V_u = rotative component of velocity, fps
d = density of air, lb per cu ft
S = area, sq ft
Q = volume, cfm
T = absolute temperature, deg F
P_b = absolute or barometric pressure, in. of mercury
Air hp = air horsepower
bhp = brake horsepower
e = mechanical efficiency
N = rpm
D = diam of fan wheel, ft
A = fan outlet area, sq ft

FUNDAMENTAL FORMULAS

Pressure, as usually understood, is called **static pressure** in fan engineering and is measured above barometric pressure. The pressure set up by velocity impingement is called **velocity pressure**; the sum of the static pressure and the velocity pressure is the **total pressure.**

Pressure in pounds per square foot is equal to the energy per unit volume in foot-pounds. Static pressure is the potential energy, velocity pressure is the kinetic energy, and total pressure is the total energy per unit volume.

Fan pressures are determined from readings of duct pressures. The **total pressure rise** p of a fan is the increase in total pressure through the fan as indicated by a differential reading between two impact tubes facing the air current, one in the fan inlet and one in the fan outlet.

The **static pressure** of a fan p_s is the total pressure rise p diminished by the velocity pressure in the fan outlet.

The **velocity pressure** of a fan p_v is the velocity pressure in the fan outlet.

Velocity. The velocity pressure, p_v, is conventionally expressed in in. of water. The relation between p_v and the velocity of a gas of density d lb per cu ft is given by

$$V = 18.3\sqrt{p_v/d} \text{ fps} = 1096\sqrt{p_v/d} \text{ fpm}$$

Air horsepower, or fan power output, is the horsepower determined from the product of the volume of air Q and the pressure rise p

$$\text{Air hp} = \frac{62.3pQ}{12 \times 33{,}000} = 0.0001575pQ$$

where p is in in. of water.

For a small pressure rise, the equation hp $= 0.2616Q(p_2 - p_1)$ may be used. For higher pressures, this equation holds when the mean effective pressure p_e is substituted for $(p_2 - p_1)$. For more accurate values, see under Air Compression, p. 319.

Table 2 gives values of p_e for various values of $p_2 - p_1$ when $p_1 = 14.7$.

Table 2. Mean Effective Pressures

$(p_2 - 14.7)$ lb per sq in.	1	2	3	5	10	15	20	30	40
p_e, lb per sq in.	0.97	1.9	2.8	4.5	8.2	11.4	14.2	19.1	23.2

When the centrifugal compressor is water-cooled—which is generally the case for pressures above 35 lb per sq in gage—it is common to refer the performance to theoretical **isothermal compression** rather than to adiabatic compression. In this case, the theoretical horsepower is

$$P_g = 0.0035Qp_1 \log_{10}(p_2/p_1)$$

Table 3 shows the theoretical horsepower for isothermal compression when the inlet pressure p_1 is 14.7 lb abs. It also shows the ratio of the theoretical isothermal horsepower to theoretical adiabatic horsepower.

Table 3. Theoretical Isothermal Horsepower

Final press, lb per sq in, gage	30	35	40	50	60	70	80	100	120
Isothermal hp per 100 cfm	7.1	7.8	8.4	9.5	10.4	11.2	12.0	13.2	14.2
$\frac{\text{Isothermal hp}}{\text{Adiabatic hp}}$	0.845	0.83	0.815	0.799	0.782	0.766	0.755	0.733	0.714

Losses

Hydraulic Losses. The actual total head produced is always less than the theoretical head H because of the hydraulic losses occasioned by friction of the gas in passing through the compressor, because of shocks and eddies caused by abrupt changes in velocity or direction of flow, and because of leakage losses. The ratio of the actual total head produced to the head theoretically obtainable is termed the **pressure coefficient.**

The **hydraulic efficiency** is the ratio of the theoretical horsepower to the fluid input horsepower, or $e_h = 509p_1Y/d_1H$.

For $d_e = 90$ deg,

$$e_h = \frac{214{,}166p_1Y}{su_a^2[1 + (v_s/u_a)\cos b_a]}$$

With a small pressure rise, and $d_e = 90$ deg,

$$e_h = \frac{60{,}600(p_2 - p_1)}{su_a^2[1 + (v_a/u_a)\cos b_a]}$$

The hydraulic losses affect the pressure rise as well as the power required; **mechanical losses** affect the horsepower also. The mechanical losses are *bearing losses* due to friction and *rotation loss*, or disk friction of the impellers.

The order of magnitude of these losses is indicated by the following values, from Kearton, for an uncooled centrifugal compressor, expressed as percent of the power input:

Hydraulic losses: surface friction of gas, 5.2; shock and eddy losses, 5.5; loss due to increase in indicated work due to non-cooling, 1.5; leakage, 2.0. *Mechanical losses:* disk friction, 7.23; bearing friction, 1.57. Total losses, 23.00.

The ratio [illegible] ɔwer required at the compressor coupling, which includes all [illegible] hanical as well as hydraulic, to the theoretical horsepower [illegible] haft efficiency e_s.

In many installations, the fan velocity pressure is wasted and only the static pressure is useful. For static-pressure power p_s is substituted for p.

The efficiency of a fan is the ratio between the horsepower output (air hp) and the horsepower input (bhp). e = air hp/bhp.

The static efficiency of a fan is the ratio between the static-pressure power and the horsepower input.

Standard air density is 0.075 lb per cu ft. This figure is the weight of 1 cu ft of air under average conditions of temperature, humidity, and barometric pressure. Manufacturers' publications of tables and curves are usually based on this standard air density.

The approximate air density is $d = 1.325P_b/T$, where P_b is the barometric pressure in in. of mercury and T is in deg F abs. For most fan testing and calculation, the density determined by this formula will introduce no appreciable error.

Fan pressures and horsepowers vary directly as the air density

Fan Characteristics

The performance of a fan can best be presented graphically. The accepted chart uses volumes as abscissas and pressures, horsepower inputs, and

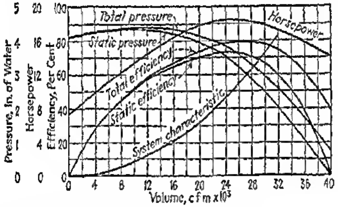

FIG. 1.—Fan Characteristics.

efficiencies as ordinates. The forms of the pressure and horsepower curves depend on the type of blading. They are characteristic of the particular type. Figure 1 shows a typical standard form of plotting of fan performance, with total pressure, static pressure, horsepower, and total and static efficiencies. Curves of the Fig. 1 plotting are necessarily drawn for a given size fan at a given speed.

Other plottings of more general application are also used. Fans function in close agreement with dimensional theory, and dimensionless plotting of fan curves is common practice.

A simple form of dimensionless plot is shown in Fig. 2. The abscissas are in percent of volume at zero static pressure, the wide open volume. The ordinates of the pressure curves are in percent of maximum pressure. Similarly horsepowers are in percent of maximum. Efficiencies are without dimension and are not changed. With the percent scales for abscissas and ordinates of a similar order of magnitude, this plotting preserves the characteristic shapes of the curves. For other forms of plotting, see p. 1682.

System Characteristics. The pressure required to deliver air through a resistance depends on the volume of flow. The relation between volume and

Speeds of Compressors. The larger the volume to be handled, the larger must be the diameter of the impeller, if proper proportions are to be maintained. On account of centrifugal stresses, tip speeds are limited by the available materials for the impellers, and the larger the impeller diameter, the lower the speed. The following table gives representative maximum rpm for various sizes of compressors:

Table 4. Representative Compressor Speeds

Inlet, vol, cfm.	1,300	2,300	4,000	7,000	12,000	20,000	28,000	40,000	60,000	90,000
Speed, rpm.	25,000	19,000	14,000	10,000	8,400	6,600	5,500	4,500	3,800	2,700

In practice, higher or lower speeds may be employed, depending on the type of impeller and the available driving units. Extremely high speeds are obtained only with exhaust gas-turbine drive.

Efficiency of Compressors. For estimating purposes, a round figure of 70 percent may be taken as the adiabatic efficiency of good uncooled centrifugal compressors at designed load conditions. The following table gives representative commercial efficiencies of centrifugal compressors of good proportions for various rated capacities.

Table 5. Representative Compressor Efficiencies (No Water Cooling)

Inlet vol, cfm.	1,300	2,300	4,000	7,000	12,000	20,000	28,000	40,000	60,000	90,000
Adiabatic eff.	0.60	0.635	0.655	0.675	0.69	0.71	0.715	0.72	0.735	0.74

Higher efficiencies have been obtained in practice; blast-furnace blowers and single-stage blowers of large capacity have shown well over 80 percent adiabatic efficiency on test. As a rule, however, extremely high efficiency calls for expensive refinements which are generally not commercially justifiable. Abnormally long and narrow impellers may show poorer efficiencies than indicated above, such wheels being sometimes used to avoid high rpm.

The performance of water-cooled compressors is generally referred to theoretical isothermal compression. Three methods of cooling may be used.

1. Cooling of the Diffusers Only. This method is generally used with moderate pressure (30 to 40 lb gage) and serves mainly to reduce the final temperature of the compressed gas. The saving in horsepower is not appreciable.

2. Cooling by Means of Water Jackets. This method is used for pressures from 35 to 100 lb gage and over. The available cooling surface is limited and jacket cooling is generally used up to about 70 lb only. Figure 9 shows a compressor for pressures up to 70 lb gage with jacket cooling.

3. Cooling by Means of Intercoolers. With this method, the compressed gas is led out of the compressor at intervals during compression and returned to the succeeding stages after cooling.

The following table shows representative efficiencies (referred to isothermal compression) of water-cooled centrifugal compressors, for various rated capacities:

Table 6. Representative Compressor Efficiencies
(With Water Cooling)

Inlet vol, cfm.	5,000	7,500	10,000	20,000	30,000
Isothermal eff, waterjacketed comp., 70 lb gage.	54	57	59	60	60
Isothermal eff, intercooled comp., 100 lb gage.	60	63	64.5	66	66

Centrifugal Compressor Constants and Characteristic Curves

Quantity Constant. The quantity of gas delivered by a centrifugal compressor is proportional to $u_a D_a b_a$, or quantity constant $= Q/u_a D_a b_a$.

pressure can be plotted to give a curve, the system characteristic. The system characteristic is best plotted with volumes as abscissas and pressures as ordinates. It is shown on the fan characteristic chart Fig. 1. The crossing point of the system characteristic and the fan pressure characteristic is the point of operation.

The fundamental system characteristic is that of the fixed resistance system. In such a system, the pressure varies as the square of the volume, giving a simple parabolic curve. Most discussions of the relation of system and fan characteristics are limited to this parabolic form. Other characteristics are empirical, and are of limited use.

Compound system characteristics are frequently encountered. Further consideration may permit their analysis into a combination of fixed resistance systems. An important one is the multiple-nozzle arrangement for steam-boiler combustion. The resistance is due to the duct losses, which are substantially parabolic, *to which is added the constant pressure required for* nozzle combustion. The addition can be made for each nozzle giving isolated points each one of which determines its own fundamental parabolic *characteristic.*

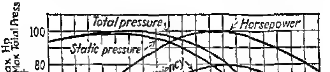

FIG. 2.—Dimensionless Plot of Fan Characteristics.

Equivalent Orifice. The equivalent orifice is a useful concept. If the total pressure delivered to a system is converted to velocity, the equivalent orifice of the system is the area which, multiplied by that velocity, gives the volume flowing through the system. Physically, the equivalent orifice may be considered an ideal nozzle of 100 percent coefficient of discharge. The term is an old one in fan engineering and originally was the equivalent thin plate orifice of the same effective area as above. Allowance was made for the vena contracta with a coefficient of 0.625. This coefficient is subject to modification by stream forms, and the ideal nozzle concept avoids such confusion.

Orifice ratio O is a dimensionless number that serves to relate the performance of geometrically similar fans of different sizes.

$$O = Q/D^2\sqrt{2gP/d}$$

where P is in pound foot units.

This true orifice ratio is equal to the equivalent orifice $Q/\sqrt{2gP/d}$ divided by D^2, or by the fan-outlet area which is proportional to D^2, since the square

Compressor Constant. A compressor model can be used with practically the same efficiency for various combinations of quantity and pressure such that $K = Q/\sqrt{p_e}$, where K is the compressor constant, Q and p_e are the desired quantity and mean effective pressure, respectively. The compressor constant can be more conveniently written as $K = QN^2/p_e^{3/2}$.

Similar Compressors. Two compressors are similar when they have the same compressor constant. In similar compressors, all impeller and discharge-vane linear dimensions are in the same ratio as their impeller diameters, and their impeller and discharge vane angles are, respectively, equal. For the same rpm, the quantities delivered by similar compressors will vary as the cubes of their diameters, the pressures will vary as the squares of their diameters, and the shaft powers will vary as the fifth powers of their diameters. For the same wheel speed, the quantity and the power will vary as the square of the diameter, but the pressure will remain constant.

Compressor Coefficients. In order to make the tests on different compressors, or on the same compressor under different circumstances, comparable on a common basis, various coefficients are computed corresponding to the given observations and these coefficients are plotted as **characteristic curves.** From these curves the pressure, power, and hydraulic and shaft efficiencies can readily be computed for any quantity of gas and any rpm. The departure of the ratio v_a/u_a from that value for which the compressor was designed determines largely the efficiency of operation. Therefore, v_a/u_a or its equivalent Q/u_a is generally used as the abscissa for the characteristic curves of a compressor, and it is designated as the **load coefficient** C_e. It is also frequently represented by Q/N. The **fluid input coefficient** (C_i) represents the horsepower corresponding to any given observation divided by the cube of the wheel speed. For the case of axial impeller inlet and radial impeller exit, $C_i = 0.00000432Qs/u_a \doteq 0.00000432C_e s$. Evidently the characteristic curve of C_i against C_e is a straight line making an angle with C_e whose tangent is $0.00000432s$; it may be drawn independently of the actual observations. In general, $C_i = 0.00000216sQV^2/u_a^3$, where $V^2 = 2gH = u_a^2 + w_a^2 - v_a^2 - u_e^2 - w_e^2 + v_e^2$. The **pressure coefficient** for normal air corresponding to the observed pressure rise ($p_2 - p_1$), is $C_p = YT_1/u_a^2$. The **theoretical power coefficient** is $C_t = 0.02571C_eC_p$. The characteristic curve for C_t should be computed and drawn from readings from the *smooth* curve of C_p against C_e. The **shaft power coefficient** is C_s = shaft hp$/u_a^3$. The **rotation loss coefficient** is $C_r = 0.0737 \times 10^{-6} D_a^2 d_m$, where d_m is the average density of the gas between p_1 and p_2, lb per cu ft. By adding the values of C_r to the values of C_i, a characteristic curve (practically a straight line) of fluid input plus rotation loss is obtained, and this curve will, in a correctly designed compressor, nearly touch the shaft power characteristic curve at the value of Q/u_a corresponding to the rated load of the compressor.

Hydraulic and Shaft Efficiencies. The ratio of C_t to C_i for any value of C_e gives the hydraulic efficiency e_h for that particular load. (For $C_e = 0$, the general formula $e_h = 6{,}080\ C_p$ must be used.) Similarly, ratios of C_t to C_s give values of e_s, the shaft efficiency. The efficiency curves thus obtained will of course be smoother and more reliable than if the efficiencies were computed directly from the individual observations of pressure and power.

Uses of Characteristic Curves. Besides affording smooth curves of hydraulic and shaft efficiencies, a set of characteristic curves as shown in

of the wheel diameter is directly proportional to the fan areas in any line of geometrically similar fans.

The conventional orifice ratio is simpler to calculate and has a different numerical value. It departs from the fundamental units, and the ratio between equivalent orifice and fan area is less apparent. For convenience g is considered constant, d taken as standard air, and p in inches of water. The ratio remains dimensionless only if the dimensions of the changes are understood.

$$O = Q/D^2\sqrt{p}$$

At constant orifice ratio and constant density, for fans of geometrically similar design, the following relations are valid:

$$Q \propto D^3N$$
$$p \propto D^2N^2$$
$$\text{Hp} \propto D^5N^3$$

For any given fan, D is constant, and at constant orifice ratio the fan laws are (1) volume varies directly as the speed, (2) pressure varies as the square of the speed, and (3) horsepower varies as the cube of the speed.

For fans of different sizes but at the same tip speed πND, the volume and horsepower vary as D^2, pressure remaining constant.

For a given orifice ratio, the velocity relations of air flow to blade speed are constant, and the efficiency of geometrically similar fans is independent of size or speed throughout a wide range. This principle is the basis of the fan industry and is used by fan manufacturers in preparing the tables and charts that they publish. An example of such a chart is the Hagen chart, Fig. 17.

DESIGN OF CENTRIFUGAL FANS

Casing. The fan casing collects the air delivered from the impeller and directs the flow into the connected duct. It is commonly a *spiral* or *scroll*. The sides of the casing are plane and parallel. In such a space, the law of the constancy of the moment of momentum, or circulation, requires the spiral to be logarithmic.

$$\theta - \theta_0 = K \log (r/r_0)$$

Figure 3 shows a typical layout of fan spiral.

More complex forms of housing are sometimes used for various reasons. But performance at high efficiency is more readily secured with the simpler logarithmic casing.

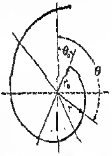

Fig. 3.—Logarithmic Spiral.

The value of the constant K can be determined aerodynamically as the ratio of the tangential component to the radial component of the air velocity leaving the fan wheel. This rational procedure usually results in a casing which is much too large for commercial consideration.

Experiment shows that the inner edge of the fan outlet may be located on the center line of the fan and the spiral swept from this point around to form an outlet substantially square. The outlet area should give a velocity pressure 10 percent of the static at the specified volume. K is then determined by trial and error to give the required sweep. Figure 4a shows a conventional spiral so determined.

Fig. 3 enables one readily to draw reliable pressure and power curves against quantity for any given wheel speed or rpm. *In that case, the load-coefficient* scale may be replaced by a quantity scale, and the readings of the C_p and the C_s curves will give the data for the corresponding pressures and powers. (In Fig. 3 the wheel speed has, in all the coefficients, been replaced by the rpm.) The system of characteristic curves is found to hold true for various sizes of centrifugal compressors, centrifugal blowers, and centrifugal pumps, giving in each case consistent curves regardless of the actual speeds, pressures, and powers. Only in ventilating-fan blowers do there seem to be occasionally some serious discrepancies near the point of maximum efficiency.

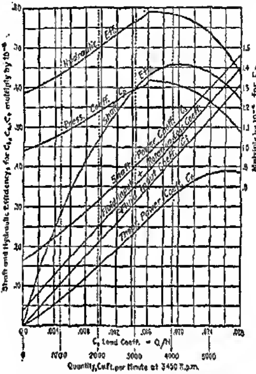

FIG. 3.—Characteristic Curves of a Centrifugal Compressor.

Numerical Examples

Power Required. Find the power required to compress adiabatically 20,000 cu ft of air per min from atmosphere to 30 lb per sq in. gage, the shaft efficiency of the compressor being 75 percent.

SOLUTION: From Table 1, the theoretical horsepower is 8.4 × 20,000/100 = 1,680 and the shaft hp is 1,680/0.75 = 2,240.

Equivalent Suction Pressure. What suction can be obtained with a compressor rated to deliver 2,500 cu ft of air per min against 2 lb per sq in. gage?

SOLUTION: The compressor is rated for an *initial* pressure of 14.7 lb per sq in. Since the *pressure ratio* depends only on the wheel speed, the hydraulic efficiency, and the initial temperature, all of which are supposed to remain the same, the initial suction pressure is (14.7/16.7) × 14.7 = 12.94 lb per sq in. abs and the suction obtained is 14.70 − 12.94 = 1.76 lb per sq in.

Equivalent Pressure when Compressing Gas. What pressure can be obtained when compressing water gas with a standard unit rated 25,000 cu ft of air per min

Modern design allows wide variation in fan outlet area for a given wheel. But a good proportion, which conforms to the 10 percent rule above, is

$$A = 1.5D^2$$

Calculations for casing of Fig. 4a. $D = 2$ ft; $A = 6$ sq ft; $\sqrt{A} = 2.45$ ft $= r_1$; 3 in. = distance to cutoff; $r_0 = \frac{D}{2} + \frac{3}{12} = 1.25$ ft; $\theta_0 = 90$ deg; $\theta_1 = 360$ deg; $\theta_1 - \theta_0 = K \log (2.45/1.25)$ deg; $K = 922$. Equation of spiral $\theta - 90 = 922 \log (r_1/1.25)$.

Cutoff. There must be a transition from the spiral flow in the housing to the straight line flow in the connected duct. Figure 4b shows the application of the principle of directing vanes to accomplish this result. Tests show that the value of this multiple vaning is negligible. The inner vane, the cutoff sheet, is worth while; the commercial casing most used is as indicated in Fig. 4c. The cutoff sheet extends into the outlet 10 to 40 percent, the lesser amount for the backwardly curved blade fan wheels and the greater amount for forwardly curved blade fans.

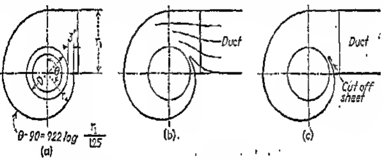

FIG. 4.—Fan Casing Scrolls.

The cutoff sheet continues the curve of the spiral. The nearest point of the cutoff sheet to the wheel should be from 3 to 5 in. in a fan of 3 ft diam. Larger diameters require a greater distance, and smaller wheels permit less. Exact proportion is not necessary as noise rather than efficiency is the determining factor in fixing this dimension.

Width of Casing. The rule given for the size of the fan outlet, *i.e.*, a velocity pressure 10 percent of the static, and the desideratum of a substantially square outlet determine the width of the casing as well as the angle, or throw, of the spiral.

Commercial fans are probably the best guide to theoretically indeterminate dimensions. Fan housings are frequently standardized for a given wheel diameter and the same housing used for fan wheels of different types. Tests indicate consistently good performance. The discovery—a purely empirical one—that forwardly curved blade and backwardly curved blade wheels would operate successfully in the identical housing has indicated that the amount of the cross-sectional area in the housing is more important than the disposition of that area.

The flow in the casing is a complex action of a spiral flow around the fan shaft center line and a vortex around the spiral center line of the casing. This latter vortex continues spinning down the outlet duct. It can be changed, and sometimes eliminated, by changing the position of the wheel axially in the housing. Such change does not affect the true fan performance. The

and 15 lb per sq in. gage, and what power will be required if it requires 2,000 hp to compress the air to 15 lb pressure?

SOLUTION: The density of water gas is 0.05167, and its specific gravity (compared with air) is 0.677. The mean effective pressure (mep) corresponding to 15 lb per sq in. is 11.4 for air (see Table 2). For water gas, everything remaining the same, mep = $11.4 \times 0.677 = 7.72$ lb per sq in., and the corresponding final pressure is 9.3 lb per sq in. gage. The theoretical power for the air rating (from Table 1) is $4.99 \times 25{,}000/100 = 1{,}248$ hp. For water gas, the theoretical horsepower is $1{,}248 \times 0.677 = 845$ hp, and the actual power $= 2{,}000 \times 0.677 = 1{,}354$ hp.

Equivalent Rating at Other Speeds. A standard centrifugal compressor rated 4,500 cu ft of air and 15 lb per sq in. pressure is to be speeded up from 3,450 to 4,000 rpm. What increase of pressure and of quantity will result?

SOLUTION: The mep for 15 lb per sq in. is 11.4. At 4,000 rpm, it will increase to $(4{,}000/3{,}450)^2 \times 11.4 = 15.33$, and the corresponding final pressure from Table 2 is 22.05 lb per sq in. abs. Also the new quantity will be $(4{,}000/3{,}450) \times 4{,}500 = 5{,}220$ cu ft per min if the same ratio of u_e/v_e, and therefore the same hydraulic efficiency is to be maintained. See Quantity Constant and Load Coefficient, pp. 1660, 1661.

General Problem. What standard compressor can be used to exhaust 18,500 cu ft of anthracite producer gas per minute against a suction of 7 lb per sq in.? The compressor is to be installed 2,000 ft above sea level. What horsepower is required?

SOLUTION: The barometer at 2,000 ft altitude is 13.56. The compressor is therefore required to compress the gas from $13.56 - 7.00 = 6.56$ lb per sq in. abs to 13.56 lb. This is equivalent to compressing the gas at sea level to a final pressure of $(13.56/6.56) \times 14.7 = 30.4$ lb per sq in. abs, or 15.7 lb gage. The density of anthracite producer gas is 0.065 lb per cu ft. The mep corresponding to 15.7 final pressure is (Table 2) 11.9 lb per sq in. The corresponding mep for air is $(0.0764/0.065) \times 11.9 = 14.0$, and the final pressure from Table 2 is 19.4 lb per sq in. gage. Suppose the nearest standard compressor is rated 16,000 cu ft per min, and 15 lb per sq in. at 3200 rpm. The mep for 15 lb is 11.4 and for 19.4 is 14.0. The standard compressor must therefore be speeded up to $3200 \times \sqrt{14/11.4}$, or 3,540 rpm. For a constant "load coefficient" Q/N, the new quantity will be $16{,}000 \times 3{,}540/3{,}200 = 17{,}700$. So if it is desired to use the standard compressor and save the extra cost of a special size, then only 17,700 cu ft per min of the gas can be exhausted with a suction of 7 lb per sq in. gage; or the compressor can be speeded up to handle 18,500 cu ft per min, but the suction will be somewhat above 7 lb. If the horsepower required by the standard compressor is 1,300 (corresponding to a shaft efficiency of 0.615) the horsepower for the desired conditions will be $1{,}300 \times (17{,}700/16{,}000) \times (11.9/11.4) = 1{,}495$.

Relative Proportions of Parts. The **impeller hub diameter** is generally 1 to 2 in. larger than the shaft diameter and usually between $\frac{1}{4}D_a$ and $\frac{1}{3}D_a$. The **casing inlet diameter** D_c is determined by the velocity desirable to allow in the annulus between the casing inlet and the impeller hub and varies generally between $\frac{1}{3}D_a$ and $\frac{2}{3}D_a$. For an axial-inlet type D_c (in.) $= 12(Q/KN)^{\frac{1}{3}}$, where Q = quantity, cu ft per min, N = rpm, and $K = 1$ for single-inlet impellers and 2 for double-inlet impellers. In radial-inlet-type impellers the **impeller inlet diameter** is $\frac{3}{4}$ to $1\frac{1}{2}$ in. larger than D_c, to allow the air to turn into a radial direction before striking the impeller blades. In axial-inlet-type impellers, the outer diameter of the impeller inlet blades is just sufficiently smaller than the casing inlet diameter to allow for mechanical clearance. The total **axial width of blade** at the inlet (on both sides of the impeller web in a double-inlet impeller) is $\frac{1}{6}D_a$ to $\frac{1}{3}D_a$; at exit, $\frac{1}{6}D_a$ to $\frac{2}{3}D_a$. Frequently the impeller exit width is designed to give a sufficiently small discharge-vane angle, and then the blade is made of constant over-all width (parallel edges). The **number of impeller blades** z_i should be as small as possible consistent with the proper guiding of the gas. The usual number is between 16 and 24, with an equal number of half blades at the outer periphery, if necessary.

determination of the axial location of the wheel in the casing is a matter of structural advantage.

Fan Inlet. The fan inlet is a converging passage, preferable curved, leading from the ambient air or from an inlet duct to a smaller diameter at the entrance to the fan wheel. Some designs are improved by a small expansion of the inlet piece immediately before the wheel—the so-called *Venturi passage.* The upstream large end of the inlet should have an area substantially equal to the fan outlet. The smaller end at the wheel is determined by the wheel proportions and may reduce in area of passage as much as 40 percent.

The clearance between inlet and impeller is important; the clearance requirements are different with different fan types. In the backwardly curved blade fan, the inlet clearance should be small, of the order of ⅛ in. in a 3 ft diam fan. The volume recirculated through a large clearance reduces the fan output materially if clearance is as much as ½ in. With radial-blade fans, moderate clearance variations have little effect. And with the forwardly curved blade type, a large clearance not only does not harm the performance but actually is necessary for stability to minimize pulsation.

Inlet Ducts. Recent investigations have emphasized the important effect on fan performance of the actual inlet connections. The ducts leading to and from a fan are designed usually to escape beams and other limitations of space, and such duct work may seriously affect fan performance. The variation in the form of ducts is so great that no rules can be given for particular application. Figures 5, 6, and 7 show three general forms.

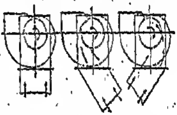

FIG. 5. FIG. 6. FIG. 7.
Inlets of Fan Casings.

In Fig. 5, the air is brought straight up to an inlet box, making a right-angle bend to get into the fan inlet. The loss in efficiency, which in this case shows itself in a drop in pressure, will amount to approximately 15 percent. This large loss is not explainable by any friction or eddy-current loss in the connection itself but is due to the poor distribution of the air flow into the wheel.

In Fig. 6, the air is led into the inlet box at an angle and will tend to produce a spin in the direction of wheel rotation. This action will reduce the horsepower taken by the fan and will decrease the efficiency. This decrease in efficiency is due to decrease in pressure of a much larger percentage than the decrease in horsepower. In extreme cases, this form of connection has reduced the pressure to one-half that which the fan is capable of supplying with open inlets.

In Fig. 7, the connection is brought in from the other direction, producing a spin against the wheel rotation. In this case, there is little or no decrease in the fan pressure. The decrease in efficiency is large, however, and shows itself as an increased horsepower. An increase in horsepower of 25 percent is quite usual and may go as high as 50 percent.

Fans should be selected from tests made with the inlet connection in place. Laboratory research can determine suitable inlet ducts, called conventionally inlet boxes, of such proportions that the fan performance is affected only slightly. With such a box, even angular connections, with suitable vaning to give straight flow into the tested inlet box, will give satisfactory results.

The absolute velocity of the gas w_e is computed from Q, D_e, and the axial width of the blade (radial-inlet type). u_e is computed from D_e and the rpm. The ratio w_e/u_e gives the tangent of the impeller inlet angle b_e (absence *of impeller inlet guides, which is the usual case, is assumed*). For the axial-inlet type, w_e is the *average* velocity in the annulus between the hub and the casing inlet and u_e and b_e vary with the diameter, giving a helical edge. The **impeller inlet passage height** is the perpendicular from the tip of a blade to the surface of the next blade. Its theoretical value is $(\pi D_e \times \sin b_e)/z_i$, and this should be increased by 10 to 30 percent. The rpm is generally determined by that of the driver or by other considerations. From the formulas given before for pressure rise, the wheel speed u_a and the outer **impeller diameter** D_a can then be determined by assuming a reasonable value for the hydraulic efficiency e_h. The rotation loss should now be computed to make sure that it is not excessive in comparison with the theoretical horse power. The impeller stresses should also be computed to see that they are not excessive for the available material. Increasing the number of stages will reduce both the rotation loss and the stresses. The inner diameter of the **discharge vanes** should be $1.1D_a$ *to* $1.2D_a$. Three to six vanes are ample for most purposes. The overlap of one vane on the other, or the definite passage between vanes, need not be very great. The **discharge vane angle** d_a is found in the same way as explained for b_e, the inlet gas quantity being multiplied by a compression factor according to the wheel speed u_a, as per Table 7. Generally, d_a is made between 3 and 5 deg. The theoretical **passage height** of the discharge vanes (perpendicular to the axial width) is $(\pi D_a \sin d_a)/z_d$, where z_d is the number of discharge vanes (same axial width of impeller and discharge vanes is assumed). The actual passage height should be 50 to 100 percent larger.

Table 7. Compression Factors

Impeller wheel speed, ft per sec.	200	250	300	350	400	450	500	550	600	650	700
Compression factor	0.989	0.982	0.974	0.965	0.955	0.944	0.931	0.917	0.903	0.888	0.871

Centrifugal-compressor Tests. Instructions for testing centrifugal compressors and for correcting test results to guaranteed conditions are given in the A.S.M.E. Test Code for Centrifugal Compressors and Exhausters, Part 1.

For **measuring volumes**, a nozzle with well-rounded inlet and smooth polished internal surfaces, proportioned as defined in the A.S.M.E. Test Code, should be used (see p. 1805). The diameter should be selected so that the required range of volume can be obtained with a total pressure drop (including velocity head) of not less than 10 or more than 40 in. of water. If greater pressure drops are required, the usual simplified formulas require correction. For air under usual atmospheric conditions, the following table will serve to give a preliminary estimate of the necessary nozzle diameter.

Diam of nozzle, in.	2½	3¼	4¼	5½	6¼	8½	11½	16	20
Cfm at 10 in. press drop	425	720	1,225	2,050	2,650	4,900	0,000	17,500	27,500
Cfm at 40 in. press drop	850	1,440	2,450	4,100	5,300	9,800	18,000	35,000	55,000

Classification

Centrifugal compressors are generally employed for pressures in excess of 1 lb gage. For lower pressures, conventional types of fans and blowers are used. Three basic classifications are in general use: Single-stage, usually

Untested inlet connections built by the tinsmith should be avoided or proper allowance made.

Outlet Connections. The transition from the spiral flow in the housing to the flow in the duct is a turbulent change with an action similar to that of abrupt expansion. Outlet ducts continuing the fan outlet area serve to convert a portion of the high velocities into static pressure. Expanding outlet connections naturally convert a large portion of the initial velocity pressure, but, due to the varying directions of the fan outlet flow, they are not as effective as would appear. They return only 50 to 70 percent of the reduction in the velocity pressures as gain in static.

Diffuser Casing. The diffuser casing permits a circumferential discharge of air, a discharge suitable when the air is delivered into a large open space. The diffuser consists of two stationary plates continuing the sweep of the side plates of the wheel and leading the air outward to a large diameter.

The diffuser functions to convert velocity into static pressure by increasing the radius of the air spin and by increasing area. In the diffuser, no energy is imparted to the air, and constant energy requires constant circulation. Circulation is the product of tangential velocity *times the circumference*, and *constancy of circulation* requires a tangential component varying inversely with the radius.

A diffusion of the radial component of the velocity also takes place owing to an increase of area with increasing radius, but no quantitative predetermination of conversion is possible as the discharge from a fan impeller is not continuous. The discharge consists of jets from the spaces between blades, and the radial expansion of these jets does not follow any simple formula. Figure 8 shows a typical arrangement of fan and diffuser casing.

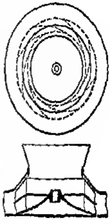

FIG. 8.—Fan and Diffuser Casing.

In general, diffusers and fan housings are designed empirically with some help from the theorem of constant circulation.

Fan Wheels. Fan-wheel proportions are subject to wide variation. Stresses in material or the combination of specified duty and speed are often determining factors. The significant proportions are the number of blades, the ratio of inlet diameter to wheel diameter, and the ratio of axial width to diameter. This latter ratio is important only as a maximum; reduced widths are always allowable.

The following table gives the proportions of fan wheels according to commercial practice:

Type wheel	Number of blades	Ratio of inlet diam to wheel diam	Ratio of width to diam
Forwardly curved	60	0.88	0.55
Radial tip	16-24	0.78	0.35
Backwardly curved	8-16	0.75	0.26
Paddle wheel	6-12	0.50-0.70	0.38-0.45

employed for air pressures from 1 to 6 lb gage, although pressures as high as 15 lb gage have been obtained with a single wheel; multistage, air-cooled, ordinarily employed for air pressures from 6 to 30 lb gage; and multistage, water-cooled, ordinarily used for air pressures from 30 to 125 lb gage.

Single-stage centrifugal compressors (turbo-blowers). Three general constructions are used.

OVERHUNG TYPE. The impeller wheel is overhung on the extended shaft of the driving machine (see Fig. 4). A very compact unit results.

PEDESTAL TYPE. The impeller wheel is supported overhung on its own shaft and has its own bearings, contained in a bearing pedestal which also may support the blower casing. The shaft is flexibly coupled to the driving machine. Figure 5 is an example of this construction.

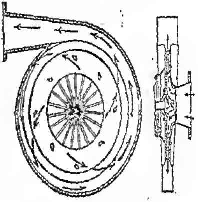

FIG. 4.—Ingersoll-Rand Single-stage Compressor.

DOUBLE-INLET TYPE. A double-sided impeller is mounted on a shaft supported by a bearing at each end, the shaft being flexibly coupled to the driving machine (see Fig. 6).

Single-stage centrifugal compressors are commonly used for supplying air to foundry cupolas and to oil and gas-fired furnaces; scavenging large two-stroke Diesel engines; supercharging four-stroke Diesel engines; pneumatic conveying of light materials; ventilating mines and tunnels; gas boosting and exhausting; emptying submarine ballast tanks; blowing coating on paper.

Multistage Centrifugal Compressors (Air-cooled). These machines are usually employed for air pressures from 6 to 30 lb gage, but, when handling gases lighter than air, may be used for lower pressures. They are built in two general types.

SINGLE INLET. The air or gas enters at one end and passes successively through the various wheels, to be discharged at the other end (see Fig. 7).

DOUBLE INLET. The number of impellers is doubled and arranged in two opposed groups. The air or gas is then drawn in at both ends and discharged at the center (see Fig. 8). This type is relatively rare in the United States, being used for exceptionally large volumes at low pressures and for larger sizes of refrigeration compressors. It is quite common in Europe.

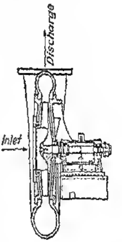

FIG. 5.—Pedestal-type Single-stage Compressor. (Roots-Connersville Blower Corp.)

For special cases, double-inlet and single-inlet impellers may be grouped in the same casing, but this construction is relatively rare.

Multistage centrifugal compressors of the uncooled type are commonly used for the following applications: blast-furnace blowing; copper-converter blowing; Bessemer-converter blowing; gas exhausting and boosting; aeration of

Fan-wheel Theory. The theory of the design of fan wheels is highly developed. The Euler equation for pressure is

$$p = (d\omega/g)[r_1V_{u_1} - r_0V_{u_0}]$$

where r_1 and V_{u_1} are the radius and rotative air velocity at exit; r_0 and V_{u_0} the quantities at entrance; and ω the rotative speed of the impeller, radians per sec. The Euler equation applies to any wheel, centrifugal or propeller.

A newer analysis, applied chiefly to propeller fans, is derived from modern aeronautics and is based on the theory of circulation around an airfoil. In airfoil theory, Γ, the circulation, is

$$\Gamma = \tfrac{1}{2}C_Lbv$$

where C_L is the lift coefficient, b the length of the chord, and v the effective velocity relative to the airfoil (see p. 1532).

Applied to a fan with a number of blades Z,

$$p = d\omega Z\Gamma/2\pi g$$

This expression for p may be equated to that of the Euler equation which, for a propeller fan with r_1 equal to r_0, becomes

$$p = d\omega r(V_{u_1} - V_{u_0})/g$$

With circulation Γ per blade,

$$r(V_{u_1} - V_{u_0}) = Z\Gamma/2\pi$$

The required circulation is then

$$\Gamma = 2\pi r(V_{u_1} - V_{u_0})/Z = C_Lbv/2$$

Values of C_L are available for published tests of airfoils (see p. 1535).

Airfoil circulation is changed by the proximity of other blades, the so-called **cascade effect**, and few quantitative data on cascade effect are available in form suitable to engineers. The practical application of airfoil wind-tunnel tests to fan-blade action is at present limited to those cases with negligible cascade effect, *i.e.*, with a spacing to chord ratio of not less than 1.5 to 2 and a low angle of attack of the order of 4 deg or less.

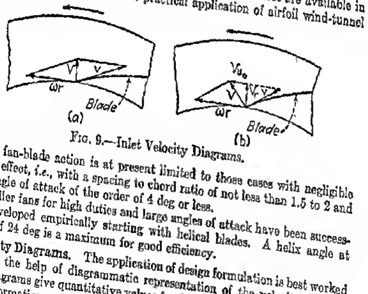

FIG. 9.—Inlet Velocity Diagrams.

Propeller fans for high duties and large angles of attack have been successfully developed empirically starting with helical blades. A helix angle at the tip of 24 deg is a maximum for good efficiency.

Velocity Diagrams. The application of design formulation is best worked out with the help of diagrammatic representation of the velocity vectors. These diagrams give quantitative values for design and, properly interpreted, much information as to the fan characteristics of different types of blading.

For centrifugal fans, the Euler analysis gives satisfactory results. The Euler theory requires separate diagrams for inlet and outlet. The inlet diagrams are always the same, as they are independent of the blading.

yeast and sewage; circulating gases in chemical plants; compressing refrigerants; pneumatic conveying.

Multistage Centrifugal Compressors (Water-cooled). Machines of this type are in common use in Europe and South Africa and are employed

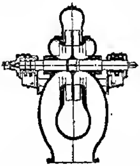

Fig. 6.—De Laval Double-inlet Single-stage Centrifugal Compressor.

to some extent in America for supplying large volumes of compressed air at pressures from 40 to 125 lb gage for mining operations, large manufacturing plants, chemical plants, shipyards, etc. They are generally similar to multistage blowers of the uncooled type, but have provision for cooling the air

Figure 9*a* shows the usual diagram for air approaching the wheel with velocity V, which combines with ωr, reversed, to give the velocity v relative to the wheel or blade. The direction of v determines the angular setting of the blade. The entrance portion of the blade may be tangent to v or inclined a few degrees from tangency dependent upon the particular blade shape contemplated.

Figure 9*b* shows the inlet velocity diagram for a positive value of an inlet spin V_{u_0} positive in the same direction as the wheel rotation. With reverse inlet spins the action produces unsatisfactory and often unstable characteristics.

Figures 10*a*, *b*, and *c* are the outlet velocity diagrams for backwardly curved, radial, and forwardly curved blades, respectively.

The height of the diagram, indicated by the velocity vector V_r, is determined in each of these cases—and also for any special inlet diagram such as 9*b*—from the design volume and the effective area through which that volume flows.

In Fig. 10*b*, the relative velocity v is tangent to the blade, ωr is perpendicular to the wheel radius. The actual air velocity V is the resultant of v and ωr. V_{u_1}, the rotative component of V, is projected from V to the direction of ωr.

FIG. 10.—Outlet Velocity Diagrams.

Velocity diagrams present a rational basis for comparing the characteristics of the three types of blading. Characteristics are determined at constant speed so the ωr vector will not change. If the volume decreases, the vector V_r decreases and, as the direction of v does not change for a given blade, V_u increases with backwardly curved blades, is constant with radial blades, and decreases with forwardly curved blades.

As the pressure of the fan depends on the product of $V_u \times \omega r$, the pressure change is the same as the change in V_u, and the pressure characteristic of the backwardly curved blade fan rises with decreasing volume, is constant for the radial blade, and decreases or falls for the forwardly curved blade. Frequently the slope of a fan characteristic is discussed in the opposite sense of increasing volumes with the designation *drooping* for the backwardly curved and *rising* for the forwardly curved blade. The decreasing volume basis is preferable as directly applicable to considerations of type desirability.

The desirable qualities of a fan are stability, successful operation in parallel, freedom from pulsation and, from the driver point of view, a non-overloading horsepower demand.

Stability. The factors of fan output are pressure and volume. Stability of operation requires that the factors change oppositely; *i.e.*, a reduction in volume should be opposed by an increase in pressure. The backwardly curved blade fan is inherently stable. The radial-blade fan is stable as to static pressure but not so where total pressure may control the action. The forwardly curved blade fan is inherently unstable.

Duct work has a characteristic also. With most ducts, the pressure decreases so much with decreased volume that even the characteristic of the

(4) GIVEN y AND s. Then $\dfrac{T}{w} = \dfrac{s^2}{2y} + \dfrac{y}{2}$, $x = \left(\dfrac{s^2}{y} - y\right) \tanh^{-1}\left(\dfrac{y}{s}\right)$; $a = \dfrac{s^2}{2y} - \dfrac{y}{2}$. Or, if y/s is small, $x = s\left[1 - \dfrac{2}{3}\left(\dfrac{y}{s}\right)^2 - \dfrac{2}{15}\left(\dfrac{y}{s}\right)^4 - \dots\right]$.

(5) GIVEN y AND T/w. Then $a = \dfrac{T}{w} - y$, $x = \left(\dfrac{T}{w} - y\right) \cosh^{-1} \dfrac{T/w}{(T/w) - y}$, $s = \sqrt{2y(T/w) - y^2}$. Or, if $y/(T/w)$ is small,

$$x = \sqrt{\frac{2yT}{w}}\left[1 - \frac{7}{12}\frac{wy}{T} - \dots\right], \quad \frac{s-x}{s} = \frac{1}{3}\frac{wy}{T}, \text{ approximately},$$

$$s = \sqrt{\frac{2yT}{w}}\left[1 - \frac{1}{4}\frac{wy}{T} - \frac{1}{32}\left(\frac{wy}{T}\right)^2 - \frac{1}{128}\left(\frac{wy}{T}\right)^3 - \dots\right].$$

(6) GIVEN s AND T/w. Then $x = \dfrac{T}{w}\sqrt{1 - \left(\dfrac{ws}{T}\right)^2} \tanh^{-1}\left(\dfrac{ws}{T}\right)$; $y = \dfrac{T}{w} - \dfrac{T}{w}\sqrt{1 - \left(\dfrac{ws}{T}\right)^2}$, $a = \dfrac{T}{w}\sqrt{1 - \left(\dfrac{ws}{T}\right)^2}$. Or, if ws/T is small,

$$x = s\left[1 - \frac{1}{6}\left(\frac{ws}{T}\right)^2 - \frac{11}{120}\left(\frac{ws}{T}\right)^4 - \dots\right], \quad y = s\left[\frac{1}{2}\left(\frac{ws}{T}\right) + \frac{1}{8}\left(\frac{ws}{T}\right)^3 + \dots\right],$$

$$a = \frac{T}{w}\left[1 - \frac{1}{2}\left(\frac{ws}{T}\right)^2 - \frac{1}{8}\left(\frac{ws}{T}\right)^4 - \dots\right].$$

Given the Length $2L$ of a Chain Supported at Two Points A and B not in the Same Level, to find a. (See Fig. 63; b and c are supposed known.) Let $(\sqrt{L^2 - b^2})/c = s/x$; enter Table 3 with this value of s/x, and find the corresponding value of the auxiliary variable z. Then $a = c/z$.

NOTE. The co-ordinates of the mid-point M of AB (see Fig. 63) are $x_0 = a \tanh^{-1}(b/L)$, $y_0 = (L/\tanh z) - a$, so that the position of the lowest point is determined.

Correction for Sag in Chaining Uphill (Fig. 64). Let l = length of tape (corrected for stretch and temperature), w = weight per unit length of tape, A = angle between the chord AB and the horizontal.

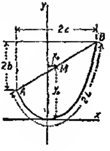

FIG. 63.

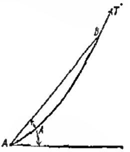

FIG. 64.

If the tension P at the upper end is known, compute wl/P and find k from Table 4. If the tension Q at the lower end is known, compute wl/Q and find k from Table 5. In either case, chord $AB = l - kl$.

NOTE. $k = 1 - \{[1 - \sqrt{1 - 2m \sin u + m^2}]/[m \sin A]\}$, where $m = wl/P$ and u is given by

$[1 - \sqrt{1 - 2m \sin u + m^2}] \sec u = [\sinh^{-1}(\tan u) - \sinh^{-1}(\tan u - m \sec u)] \tan A$.

Also, $Q = P - wl(1 - k) \sin A$, where k is the value in Table 4 corresponding to the given values of P and A.

Correction for Stretch in Chaining Uphill. Let L = unstretched length of tape at working temperature, w = weight per unit length of tape, A = angle

forwardly curved blade fan has excess pressure requirement at reduced volume and because of duct reaction becomes stable in spite of its own unfavorable characteristic.

Parallel Operation. Two or more fans operating on a single duct system must have suitable characteristics for such operation and be properly selected as to point of operation. Parallel operation requires that the sum of the outputs of the fans equal the duct capacity and that this equality exist for only one set of conditions. *In mathematical phraseology, the characteristics* of the fans and duct must be satisfied and uniquely.

Figure 11 shows the graphical analysis for parallel operation of two fans. The duct characteristic is the usual parabola, and the fan characteristic is typical of the backwardly curved blade type. One fan operating on the duct will deliver the volume and pressure of their intersection A. If an identical fan is added to the system, the volume and pressure will be greater. The exact point of operation may be determined by constructing the "limit curve." At a series of pressures such as P, plot the volumes L which when

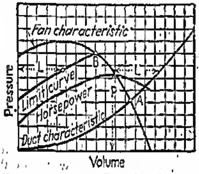

FIG. 11.—Stable Parallel Operation of Two Fans.

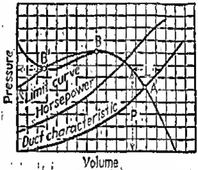

FIG. 12.—Unstable Parallel Operation of Two Fans.

added to the volume of the fan will equal the volume of the duct characteristic. Draw the limit curve through the points. The intersection B of limit curve and fan characteristic gives the point of operation of each of two identical fans.

For successful operation, there should be only one such point. Further, the intersection angle should not be small or there may be hunting. The requirements are best presented by a comparison of Fig. 11, which indicates successful paralleling, with Fig. 12, which shows an incorrect combination. Figure 12 shows the analysis for forwardly curved blade fans. The limit curve is constructed in the same manner as in Fig. 11, but in Fig. 12 there are two intersections and between them a superposition of the two curves. Any attempt to parallel fans with such characteristics will be successful only by accident. The point of equal load division in both Figs. 11 and 12 was selected for efficient operation and correctly represents the comparison of the parallel operation of the two types. It is apparent that, with a different relation between duct and fan characteristics which would permit the equal division of load to occur at a larger orifice on the fan curve, successful parallel operation is possible even with the forwardly curved blade fan, but only at a sacrifice, as this region of the fan output is in the range of low efficiency.

Figures 11 and 12 show also an important advantage of the self-limiting horsepower of the backwardly curved blade fan. When two fans are installed on one duct system, the reliability of partial load operation with one fan in

Permeability (μ) is the ratio of the magnetic-flux density to the magnetizing force ($=B/H$). Actually it is the ratio of the magnetic flux in any element of a medium to the flux which would exist if that element were replaced with air, the mmf acting on the element remaining unchanged.

Reluctivity (ν) is the reluctance between any two parallel faces of 1 cm-cube of the medium. It is the reciprocal of permeability.

Reluctance ($\mathcal{R}$) is resistance to magnetic flow. In a homogeneous medium of uniform cross section cgs reluctance is equal to the length divided by the product of the area and permeability, the length and area being expressed in centimeter units ($\mathcal{R} = L/A\mu$).

Permeance ($\mathcal{P}$) is the reciprocal of reluctance.

Current (I, i). The practical unit of current is the **ampere**, which is equal to one-tenth the absolute unit of current and is the current that flows through a conductor having a resistance of 1 ohm and a difference of potential of 1 volt between its ends. The absolute unit of current is that current which flowing in a conductor perpendicular to the lines of force in a field of unit intensity causes to be exerted on each centimeter of the conductor a (unit) force of 1 dyne. One ampere (direct current) will deposit 0.001118 g of silver per sec from a standard silver solution.

Quantity (Q). The practical unit of quantity is the **coulomb** and is that quantity which passes a cross section of the conductor in 1 sec when the rate of flow is 1 amp.

Potential Difference or Electromotive Force (E, V, emf). Electromotive force tends to cause flow of electricity. The practical unit of electromotive force is the **volt**. A conductor cutting flux at the rate of 1 maxwell per sec has induced in it one absolute unit of emf. The volt is 10^8 times the absolute unit.

Resistance (R, r). The practical unit of resistance is the **ohm** (Ω) and is that resistance through which the fall of potential is 1 volt when the current is 1 amp. The ohm equals 10^9 absolute units of resistance.

Conductance (G, g). Conductance is the reciprocal of resistance and is expressed in reciprocal ohms or **mhos** ($\mho$) ("mho" is ohm spelled backward).

Capacitance (C). The practical unit of capacitance is the **farad** (f) and is that capacitance the potential of which will be raised 1 volt by the addition of a charge of 1 coulomb. As the farad is too large a unit for practical purposes, the **microfarad** (μf), which is one-millionth of a farad, is generally used. For capacitors such as are used for radio purposes the **micro-microfarad** ($\mu\mu f$), or 10^{-12} farad, is a more suitable unit. The magnitude of the microfarad is 9×10^5 that of the cgs electrostatic unit (statfarad).

Dielectric Constant or Permittivity (κ). The dielectric constant of vacuum is unity and that for air is practically the same. The dielectric constant is the ratio of the conductivity of a dielectric for electrostatic lines to that for vacuum. Therefore, it is the ratio of the electrostatic capacitance of a given capacitor with a certain dielectric to the capacitance of the same capacitor with vacuum as the dielectric.

Self-inductance (L). The practical unit of self-inductance is the **henry**. The henry is also called the **coefficient of self-induction**. An electric circuit has an inductance of 1 henry when a rate of change of 1 amp per sec will induce an emf of 1 volt. It also follows that in such a circuit 1 amp will produce 10^8 cgs linkages of magnetic lines (product of turns and flux) in the circuit, since a change of 10^8 linkages per second is required to induce 1

the event of the failure of the other unit is usually of importance. With a self-limiting-horsepower fan, there is no possibility of overloading the driving motor. With the other types of fans, the excess load with single-fan operation on a parallel system must always be considered in selecting motors.

Pulsation. Fans used for high pressures can, under some conditions, develop a severe pulsation. No exact pressure can be stated below which this action cannot occur, but it seldom happens below 15 in. of water. In most fans at one-sixth to one-third of the design volume, there is a *blowback* out of a portion to the inlet and a definite puffiness in the discharge. Fans should not be used for the higher pressures at the blowback point.

Pulsation is most severe when the fan discharges into a large duct or chamber with a volume content 5 percent or more of the volume per minute of normal fan output. A chamber of this size can be set into violent pulsation by a fan, not only at the blowback point, but also at any portion of its characteristic curve where the slope of the curve shows decreasing pressure with decreasing volume. Pulsation can also be set up by an apparently stable fan in double-inlet arrangement when there is a large difference between the flows to the two inlets.

DESIGN OF PROPELLER FANS

Velocity diagrams for propeller fans are usually drawn for a uniform axial velocity. Figure 13 shows a typical propeller fan diagram where ωr is the reversed speed of the blade section under consideration, V_0 the axial velocity of the air, V_1 the air velocity leaving the impeller, and v_∞ the mean relative velocity drawn to bisect V_{u_1}. v_∞ is the theoretically correct velocity to use in the equation relating the circulation and the lift coefficient.

FIG. 13.—Velocity Diagram for Propeller Fan.

$$\Gamma = \tfrac{1}{2}C_L v_\infty b$$

Propeller fans are inherently of the backwardly curved blade type and have characteristic curves somewhat similar to those of that type of centrifugal fan. The propeller curves are changed in the low-volume range by an outward radial flow progressively increasing to a maximum at zero delivery. When no air is delivered from the impeller, the air flow consists of two eddies entering the impeller from both sides in the region near the hub and leaving near the tip. This action increases both pressure and horsepower. Figure 14 shows the characteristic curves of an efficient propeller fan. This fan has a small pitch angle, 15 deg at the tip. The fan performance is perfectly stable throughout the full range of the curve. This quality of stability will hold for most propeller fans up to 17 deg and with careful design, with constant circulation at the design point, even up to 20 deg. For steeper pitches, instability occurs with a break in the curve as indicated in Fig. 15.

The small-pitch angle fan has the advantage of high efficiency and stable operation. Its disadvantages are low capacity and high speed. Because of this high speed, these fans are noisy for a given duty and for the higher pressures present a difficult structural design problem.

Steep-pitch fans deliver large volumes, are less noisy, and can be built for high pressures—but all at a sacrifice of stability and efficiency.

The commercially desirable propeller fan is the medium-pitch type from 17 to 20 deg. It usually has wide blades, taking up, in projected area, more than 50 percent of the circle. The cascade ratio, spacing to chord, is less than unity.

volt. One henry is equal to 10^9 absolute units of self-inductance. If the permeability is constant, $L = n\phi 10^{-8}/I$ henry, where $n\phi$ is the cgs linkages and I is the amp.

Mutual Inductance (M). When a change of current in one circuit induces an emf in a second circuit, the two circuits are said to have **mutual inductance**. The unit of mutual inductance is the henry. When a change of current of 1 amp per sec in either of two separate circuits induces an emf of 1 volt in the other circuit, their mutual inductance is 1 henry. Also, 1 amp in one circuit produces 10^8 cgs magnetic linkages in the other circuit when their mutual inductance is 1 henry. If M is the mutual inductance of two circuits and k is the **coefficient of coupling** (*i.e.*, the proportion of flux produced by one circuit which links the other) then $M = k\sqrt{L_1L_2}$, where L_1 and L_2 are the respective self-inductances of the two circuits.

Table 1. Electrical Units

Symbol	Quantity	Equation	Practical unit	Value of practical units, electromagnetic units
I, i	Current	$I = E/Z,\ I = Q/t$	Ampere	10^{-1}
Q, q	Quantity	$Q = It$	Coulomb	10^{-1}
			Ampere-hour	360
E, e	Electromotive force	$E = W/Q$	Volt	10^8
R, r	Resistance	$R = P/I^2 = E/I$	Ohm	10^9
ρ	Resistivity	$\rho = RA/L$	Ohms per circular mil-foot	
			Ohms per centimeter cube	10^9
λ	Conductivity	$\lambda = 1/\rho$	Mhos per unit volume	
C	Capacitance	$C = Q/E$	Farad	10^{-9}
L	Inductance	$L = n\phi 10^{-8}/I$	Henry	10^9
	Time constant	L/R	Second	1
			Henry per ohm	1
T	Period of cycle	$T = 1/f$	Second	1
f	Frequency	$f = 1/T$	Cycles per second	1
ω	Angular velocity	$\omega = 2\pi f$	....	......
X_L	Inductive reactance	$X_L = 2\pi fL$	Ohm	10^9
X_C	Capacitive reactance	$X_C = 1/2\pi fC$	Ohm	10^9
X, x	Reactance	$X = X_L - X_C$	Ohm	10^9
Z, z	Impedance	$Z = \sqrt{R^2 + X^2}$	Ohm	10^9
G, g	Conductance	$G = R/Z^2$	Mho	10^{-9}
B, b	Susceptance	$B = X/Z^2$	Mho	10^{-9}
Y, y	Admittance	$Y = \sqrt{G^2 + B^2} = 1/Z$	Mho	10^{-9}
P	Electric power	$P = EI = I^2R$	Watt	10^7
		$= EI \cos\theta$ (a-c)	Watt	10^7
W	Electric energy	$W = Pt$	Joule	10^7
			Watthour	36×10^9
			Kilowatt-hour	36×10^{12}
	Power factor (p.f.)	$\dfrac{EI\cos\theta}{EI} = \dfrac{\text{real } P}{\text{apparent } P}$		
	Reactive factor	$\dfrac{EI\sin\theta}{EI} = \dfrac{\text{reactive } P}{\text{apparent } P}$		

n = number of turns; t = time in seconds; f = frequency; ϕ = flux.

Special propeller fans have been built for high efficiency and in large sizes for wind tunnels. These fans are the opposite of the commercial type. The blades are narrow compared with their radial length. The cascade ratio is 2 or more, and the lift coefficient 0.6 or less corresponding to a low angle of attack. For a given duty, such fans may be twice the diameter of the equivalent commercial fan, but with a gain of approximately 10 percent in efficiency.

Guide Vanes for Propeller Fans. The discharge from the propeller wheel necessarily has a rotation unless guide vanes are used in the inlet. The tangential component of the discharge velocity serves no useful purpose. Stationary deflecting or diffusion vanes past the wheel convert the tangential velocity into static pressure. The vanes are preferably airfoil shapes with a total circulation equal and opposite to the total circulation produced by the propeller. The number of diffusion vanes should be prime to the number of propeller blades.

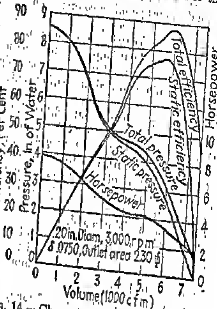

FIG. 14.—Characteristic Curves of Stable Propeller Fan.

Cascade effect must be allowed for in designing diffusion vanes also. The allowance calculations are complex. They are based on the increase of angle of attack for zero lift resulting from cascade with additional corrections for thickness and camber. A much simpler correction has given satisfactory results—within 8 percent of expected performance. This approximate method makes the correction entirely by increased camber. Figure 16 indicates the procedure. V_d is the average discharge velocity leaving the propeller, V_a the axial component of this velocity, and v_∞ the mean velocity, a factor of the vane circulation.

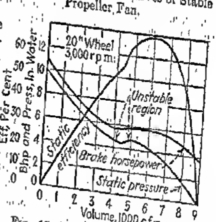

FIG. 15.—Characteristic Curves of a Propeller Fan Having an Unstable Region.

v_∞ is extended, intersecting DE, parallel to V_a, at B. A smooth arc tangent to V_d at A and to DE at B gives, to an unknown scale, the b of the equation for circulation. A suitable C_L may be selected from airfoil data and the curve AB rotated about A through the required angle of attack α to the position AC. AC is the corrected mean line of the airfoil. The scale is determined by the length b calculated from the known Γ.

$$\Gamma = \tfrac{1}{2}C_L v_\infty b$$

The chord of the selected airfoil now becomes warped to the curved line AC.

Power (P). The practical unit of power is the watt. One watt is produced when 1 amp flows under an emf of 1 volt. One watt equals 10^7 ergs per sec. One kilowatt equals 1,000 watts.

1 watt = 0.00134 hp = 44.25 ft-lb per min = 0.2389 g-cal per sec = 0.737 ft-lb per sec, = 0.0569 Btu per min.

Watts = volts × *amp* × *cosine of angle of phase* difference (or power factor) with alternating currents.

Volt-amperes or **apparent power** = volts × amp (a-c).

Energy (W). **Watthours** and **kilowatt-hours** are the units of energy used in commercial electrical work.

1 whr = 3,600 joules = 2,655.4 ft-lb = 860 IT g-cal = 3.413 Btu = 0.001341 hp-hr.

The practical unit of electrical energy is the **joule**. One watt-second equals one joule. One joule is produced when a steady current of 1 coulomb per sec., *i.e.*, 1 amp flows through a resistance of 1 ohm for 1 sec. One joule is equivalent to 0.2389 g-cal and also equals 10^7 ergs. (An erg is a dyne-centimeter.)

CONDUCTORS AND RESISTANCE

Materials. The materials generally used for the transmission and distribution of electrical energy are **copper, aluminum, iron,** and **steel.** For resistors and heaters, iron, steel, commercial alloys, and carbon are most used.

Copper is the most commonly used electrical conductor; it is always used for insulated wires and cables.

Aluminum is used to considerable extent for high-voltage transmission lines, because its weight is one-half that of copper for the same conductance. Moreover, the greater diameter reduces corona loss. It has 1.4 times the linear coefficient of expansion so that changes in sag with temperature are greater. Because of its lower melting point spans fail more readily with arc-overs. In aluminum cable steel-reinforced (A.C.S.R.), the center strand is a steel cable, which gives added tensile strength. Aluminum is used occasionally for bus bars because of its large radiating surface for a given conductance.

Steel, either galvanized or copper clad, is used occasionally for high-voltage transmission spans where tensile strength is more important than high conductance. Steel is also used for third rails.

Resistivity or **specific resistance** is the resistance of a sample of the material having both a length and cross section of unity. The resistance of a **centimeter-cube** and **circular-mil-foot** (see below) are the two most common units of resistivity. If l is the length of a conductor of uniform cross section a, then its resistance $R = \rho l/a$ (1) where ρ is the resistivity. With a cir-mil-ft ρ is the resistance of a cir-mil-ft and a is the cross section in cir mils. Since $v = la$ is the volume of a conductor $R = \rho l^2/v = \rho v/a^2$ (2).

A **circular-mil** is a unit of area equal to that of a circle whose diameter is 1 mil (0.001 in.). It is the unit of area which is used almost entirely in this country for wires and cables. To obtain the circular mils of a solid *cylindrical* conductor, square its diameter expressed in mils. For example, the diameter of 000 A.W.G. solid copper wire is 410 mils and its cross-section is $(410)^2$, or 168,100, cir mils. The diameter in mils of a solid cylindrical conductor is the square root of its cross-section expressed in cir mils.

A **circular-mil-foot** is a conductor having a length of one foot and a uniform cross section of one circular mil. In terms of the copper standard (see Table 4, p. 1692) the resistance of a circular-mil-foot of copper at 20 C is

For diffusion vane determination, this approximate method of cascade correction is satisfactory.

The same method is applicable to propeller blades but tends to give slightly higher values of C_L than are shown by the wind-tunnel tests.

Axial-flow Multistage Compressors. Axial-flow impellers and diffusion or guide vanes permit a compact multistage arrangement for high pressures. Rotative speeds need not be excessive. Efficiencies are higher than those of multistage centrifugal compressors. With a compression ratio of 4, efficiencies of about 85 percent have been obtained.

The disadvantage of the axial-flow design is its tendency to pulsate within a normal range of output. To limit the number of stages and the rotative speed, a steeply pitched blade with a large angle of attack is desirable. The pressure characteristic consequently exhibits the unstable break or dip characteristic of steep-pitch propellers, as previously referred to in connection with Fig. 15, and the break is located at from 50 to 80 percent of the design capacity. Centrifugal compressors also have a pulsation range, but at 20 to 30 percent of normal output, a percent of rating which for most applications is below the useful demand.

The field of the axial-flow compressor is therefore limited to fans with a substantially fixed resistance system (see p. 1947). An instance of such duty is the compressor end of a constant-output gas turbine.

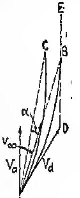

FIG. 16.—Determination of Airfoil Camber for Propeller Fan Vanes and Blades.

Multistage Compressor Theory. The same general laws apply to the action of compressors as apply to low-pressure fans. For fans, however, an implied constant density simplifies the statement of the laws. Compression requires more exact and specific discussion.

The simple fan laws (p. 1671) become for the compressor

(1) the *inlet* volume varies directly with the speed;

(2) the *work per pound* varies as the square of the speed; and

(3) the *horsepower* varies as the cube of the speed.

As the changes in velocity pressure through an axial flow compressor are a negligible proportion of the developed pressure, the increase in static pressure may be considered identical with total pressure rise.

Compressors are rated on inlet volume, pressure rise, and an efficiency based on the corresponding adiabatic work. This adiabatic efficiency decreases with increased speed and the consequent increased pressure ratio. The true efficiency of a bladed impeller is substantially unaffected by speed.

Adiabatic work and efficiency are suitable criteria from the standpoint of the purchaser, but the designer can work more readily and intelligently from a formula that allows for added heat due to an efficiency less than unity.

Multistage-compressor Design. Practicability requires minimum axial lengths per stage. Compressor impellers, therefore, have a large number of narrow blades, resembling a Parsons-turbine-rotor element. The number of blades is usually 60 to 100. Diffusion vanes are likewise many and narrow and prime to the number of impeller blades. Blades and vanes should be of streamline cross section. As streamlining in metal requires expensive die work, a uniform impeller blade and diffusion vane is preferably used for all stages. The blade height may be reduced in the later stages to allow for compression and maintain uniform entrance velocity.

10.371 ohms. As a first approximation 10 ohms may frequently be used (also see p. 1760).

At 60 C a circular-mil-inch of copper has a resistance of 1.0 ohm. This is a very convenient unit of resistivity for magnet coils since the resistance is *merely the length of copper in inches divided by its cross section in cir mils* (see p. 1772).

Max. working temperatures, C, Cu, 260; Ni, 600; Pt, 1500.
[a] 0 C. [b] Furnace electrodes, 3000 C.
(See Table 24, p. 1766, for properties of resistor alloys.)

Temperature Coefficient of Resistance. The resistance of the pure metals increases with temperature. The resistance at any temperature t C is $R = R_0[1 + \alpha t]$ (3) where R_0 is the resistance at 0 C and α is the temperature coefficient of resistance. For copper, $\alpha = 0.00427$.

With any initial temperature t_1, the resistance at temperature t C is $R = R_1[1 + \alpha_1(t - t_1)]$ (4) where R_1 is the resistance at temperature t_1 C and α_1 is the temperature coefficient of resistance at temperature t_1 (see Eq. 6).

Inferred Absolute Zero. Between 100 C and 0 C the resistance of copper decreases at a rate which is practically uniform and which if continued would give a resistance of zero at −234.5 C (an easy number to remember). If the resistance at t_1 C is R_1 and the resistance at t_2 C is R_2, then

$$R_2/R_1 = (234.5 + t_2)/(234.5 + t_1) \tag{5}$$

For any initial temperature t_1 the value of α_1 is

$$\alpha_1 = 1/(234.5 + t_1) \tag{6}$$

Example. The resistance of a copper coil at 25 C is 4.26 ohms. Determine its resistance at 45 C. Using Eq. (4) and $\alpha_1 = 1/(234.5 + 25) = 0.00385$, $R = 4.26\,[1 + 0.00385(45 - 25)] = 4.59$ ohms. Using Eq. (5) $R = 4.26\,(234.5 + 45)/(234.5 + 25) = 4.26 \times 1.077 = 4.59$ ohms.

American Wire Gage (A.W.G.). The A.W.G. (formerly Brown & Sharpe gage) is based on a constant ratio between diameters of successive gage numbers. The ratio of any diameter to the next smaller is 1.123, and the corresponding ratio of cross sec-

The ratio e of the temperature rise during adiabatic compression to the actual temperature rise has been observed to be practically constant as the speed of a fan changes. On the assumption that this is the case, the work H done in compressing 1 lb of air is

$$H = \frac{p_0V_0}{e}\left\{\frac{k}{k-1}\left[\left(\frac{p_1}{p_0}\right)^{(k-1)/k} - 1\right] - (1 - e)\log_e\frac{p_1}{p_0}\right\}$$

where p_0 and p_1 are the inlet and outlet absolute pressures (lb per sq ft) respectively, and k is the ratio of specific heats ($= 1.4$ for air). A usual value for e is 0.8 with good design. The work per stage h is given by H/z where z is the number of stages.

From the Euler equation for axial flow,

$$h = \omega r(V_{u_1} - V_{u_0})/g$$

V_{u_0}, the tangential spin at the inlet of a stage, may be zero; may be positive spin with the wheel, diminishing the possible work; or may be negative spin against the rotation of the wheel, increasing the work. This last direction of V_{u_0} will increase the tendency to and the violence of pulsation. With the V_{u_0} determined, preferably zero, V_{u_1} is evaluated.

The total circulation Γ can then be calculated. $\Gamma = 2\pi r(V_{u_1} - V_{u_0})$, and $\Gamma_b = \Gamma/Z$, where Γ_b is the circulation per blade. The blades and vanes may be designed from the lift coefficients of a high lift air foil in accordance with the procedure described for propeller fans.

SELECTION OF FAN SIZE

Fan engineering is based on tests of models. The size of the model should not be too small; 30 to 36 in. in diameter is convenient. Curves of test results may be confidently used to predict the performance of geometrically similar fans of any size larger than the model. Sizes smaller than 30 in. show poorer results and should be tested in each size.

The curves of Fig. 1 are for a 34 in. fan. The use of such curves is best explained by an example:

Required a geometrically similar fan to deliver 32,000 cfm at 0.8 in. of water, static pressure, with air at 200 F.

Select first from Fig. 1 a point of operation. The peak of the total efficiency is a desirable point.

Volume 27,000 cfm; static pressure, 3.05 in.; speed, 1,100 rpm. The curve is drawn for a density of 0.075, whereas the example has the lower density $d = 1.325 \times 29.92/660 = 0.06$. As the pressure of a fan varies as the air density, the equivalent pressure at the 0.075 of the test curve is $0.8 \times 0.075/0.06 = 1$ in. The equivalent performance of the model at this pressure is

$$\text{Speed} = 1{,}100\sqrt{1/3.05} = 630 \text{ rpm}$$
$$\text{Volume} = 27{,}000 \times 630/1{,}100 = 15{,}450 \text{ cfm}$$

At the same tip speed, the larger fan must have the same air velocities so the ratio of the two fan areas, or diameters squared, must be in proportion to the volumes. $D_L^2/D_m^2 = K^2 = 32{,}000/15{,}450 = 2.07$, where D_L is the required diameter of the larger fan, D_m the diameter of the model, and K the ratio. $D_L = 34\sqrt{2.07} = 49$ in. The speed of the large fan is $630/\sqrt{2.07} = 437$ rpm. The horsepower with 71 percent static efficiency $= 0.0001575 \times 32{,}000 \times 0.8/.71 = 5.68$.

The problem is usually complicated by the necessity of fitting the required duty to some standard diameter. The sizes given in Fig. 17 are a typical commercial standardization. A 48.5 in. wheel is the closest to the 49 in. of the tentative calculation.

tions is $(1.123)^2 = 1.261$ or 1¼ approximately. $(1.123)^6$ is 2.0050 so that diameters differing by 6 gage numbers have a ratio of approximately 2; cross sections differing by 3 gage numbers also have a ratio of approximately 2. The ratio of cross sections differing by two numbers is $(1.261)^2 = 1.590$, or 1.6 approximately. The ratio of

With a known wheel diameter, the procedure becomes inverse. $K = D_L/D_m = 48.5/34 = 1.425$. The equivalent volume for the model is $Q/K^2 = 32{,}000/2.03 = 15{,}740$. But this volume is at a speed different from that of the model test curve, as the pressure corresponding to this equivalent volume is still 0.8 at 200 F corrected to 0.075 density, or 1 in.

A parabola plotted on Fig. 1 with vertex at the origin of coordinates, passing through 15,740 cfm and 1 in. static pressure, is the locus of the volume and pressure values for changing speed with constant orifice. The orifice is set by the calculated equivalent

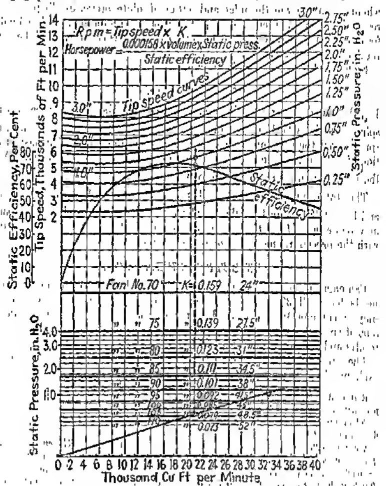

FIG. 17.—Hagen Fan Chart.

volume and the given pressure corrected. The intersection of this constant orifice curve and the static pressure characteristic of the fan gives the volume and pressure that the fan would deliver through that orifice at the speed of the test. The values at the intersection are: volume, 27,400 cfm; static pressure, 3 in; static efficiency, 70.5 percent; rpm, 1,100.

The speed of the test fan for the equivalent conditions is in proportion to the volumes, or the speed is $1{,}100 \times 15{,}740/27{,}400 = 633$ rpm. For the 48.5 in. standard fan, the speed is $633/K = 633/1.425 = 444$ at which speed and handling 200 F air the fan will deliver the required 32,000 cfm against 0.8 in. static pressure at a static efficiency of 70.5, taking 5.71 hp.

Fan Charts. Dimensionless plottings of fan data can be based on many different ratios to serve specific purposes. These plottings are not character-

cross sections differing by 10 numbers is approximately 10. The gage ordinarily extends from No. 40 to 0000 (4/0). Wires larger than 0000 must be stranded and their cross section is given in cir mils.

From *N.B.S., Circular* 31. See Table 20, p. 1763, for the carrying capacity of wires.

The diameter of No. 10 wire is 102.0 mils. As an approximation this may be considered as being 100 mils; the cross section is 10,000 cir mils; the resistance is 1 ohm per 1,000 ft; and the weight of 1,000 ft is 31.4 (10π) lb. Also the weight of 1,000 ft of No. 2 is 200 lb. These facts give many short cuts in estimating resistances and weights of various gage numbers.

Fig. 1.—*Makeup of a 19-strand Cable.*

Lay Cables. In order to obtain sufficient flexibility, wires larger than 0000 are stranded, and they are designated by their circular mils. Smaller wires may be stranded also since sizes as small as No. 4 when insulated are usually too stiff for easy handling. *Lay cables are made up geometrically as shown in* Fig. 1. Six strands will just fit around the single central conductor; the number of strands in each succeeding layer increases by 6. The number of strands that can thus be layed up are 1–7–19–37–61–91–127, etc. In order to obtain sufficient flexibility with large cables, the strands themselves frequently consist of stranded cable.

The **resistance of cables** is readily computed from Eq. (1), using the cir-mil-ft as the unit of resistivity.

istic curves in that they tend to the same form or shape for all types of fans. They are useful as criteria of the value of a design or for convenience in calculation. Most generally used is a plot of efficiencies and tip speeds as ordinates with orifice ratios as abscissas.

The upper portion of the Hagen Chart, Fig. 17, is a plot of this type. No scale for orifice ratio is given on the chart as the correct abscissa is provided for by the lower portion of the chart. This lower portion has volumes as abscissas and pressures as ordinates spaced as the square roots of the pressures. A diagonal line to the origin through a point of desired volume and pressure is the hypotenuse of a triangle of which the volume abscissa and the ordinate length of square root of pressure are the two sides.

Fan lines are located on the chart at distances from the base line proportional to $1/D^2$. The same diagonal, extended if necessary, intersects any fan line forming a triangle similar to the pressure volume triangle. From these two similar triangles the abscissa intercept along the fan line must equal $V/D^2\sqrt{p_s}$, that is, the orifice ratio. The function of the lower portion of the chart is to determine conveniently the orifice ratio for a given volume and pressure of any of the standard size fans of the manufacturers line.

Quantitative results depend on the scales. In constructing the chart the scales for volume and pressure may be selected arbitrarily for ease of reading. The scale for the location of the fan lines proportional to $1/D^2$ may also be selected arbitrarily so as to use the space on the chart to good advantage. These three scales fix the scale of orifice ratio. This scale can be calculated arithmetically if desired but it is simpler to construct the chart from a fan-test curve such as Fig. 1.

The fan line of the test-fan size is drawn in for construction purposes. A volume and corresponding pressure may then be selected from the test curve and located on the chart determining the diagonal. The intersection of this diagonal with the fan line of the test fan size gives the abscissa of orifice ratio to correct scale value. At that same abscissa on the upper portion of the chart the test efficiency may be plotted, also the tip speed of the test. Additional tip speed points are plotted at this same abscissa spaced as the square roots of the pressure. This procedure is repeated for enough points taken from the test curve to permit accurate determination of the curves of the chart.

Solving the preceding problem by the use of the chart (Fig. 17) the procedure is as follows: Through the 32,000 volume and the corrected 1 in pressure point, a straight line is drawn to the origin intersecting fan lines of the standardized sizes. Above any of these intersections can be taken off efficiency and tip speed for that particular fan. For example, above the 48.5 in. intersection the efficiency is 70.5 and the tip speed for 1 in. static is 5,600 fpm. The rpm is $5{,}600/(48.5\pi/12) = 442$.

Example. Determine the resistance of 3,500 ft of 800,000-cir mil cable at 20 C. *Ans.* ρ (of a cir mil-ft) = 10.37. R = 10.37 × 3,500/800,000 = 0.0454 ohm.

ρ = 10 ohms per cir-mil-ft is often sufficiently accurate for practical purposes.

ELECTRICAL CIRCUITS

Ohm's law states that, with a steady current, the current in a circuit is *directly* proportional to the *total* emf acting in the circuit and is *inversely* proportional to the total resistance of the circuit. The law may be expressed by the following three equations:

$$I = E/R \quad (7); \qquad E = IR \quad (8); \qquad R = E/I \tag{9}$$

where E is the emf, volts; R the resistance, ohms; and I the current, amp.

Series Circuits. The combined resistance of a number of series-connected resistances is the sum of the separate resistances. When batteries or other sources of emf are connected in series the total emf of the combination is the sum of the separate emfs. The open-circuit emf of a battery is the total generated emf, and may be measured at the battery-terminals only when no current is being delivered by the battery. The internal resistance is the resistance of the battery alone. The current which will flow in a circuit connected in series with a source of emf is $I = E/(R + r)$, where E is the open-circuit emf, R the external resistance, and r the internal resistance of the source of emf.

Parallel Circuits. The combined conductance of a number of parallel-connected resistances is the sum of the separate conductances.

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots \tag{10}$$

The equivalent resistance for two parallel resistances R_1, R_2, is

$$R = R_1R_2/(R_1 + R_2) \tag{11}$$

The equivalent resistance for three parallel resistances, R_1, R_2, R_3, is

$$R = \frac{R_1R_2R_3}{R_1R_2 + R_2R_3 + R_3R_1} \tag{12}$$

and for four parallel resistances, R_1, R_2, R_3, R_4,

$$R = \frac{R_1R_2R_3R_4}{R_1R_2R_3 + R_2R_3R_4 + R_3R_4R_1 + R_4R_1R_2} \tag{13}$$

To obtain the resistance of combined series and parallel resistances, the equivalent resistance of each parallel portion is obtained separately and then these equivalent resistances are added to the series resistances according to the principles stated above.

Kirchhoff's laws (derived from Ohm's law) make it possible to solve many circuit networks that would otherwise be difficult of solution. The first law states that: *In any branching network of wires the algebraic sum of the currents in all the wires that meet at a point is zero.* The second law states that: *The sum of all the electromotive forces acting around a complete circuit is equal to the sum of the resistances of its separate parts multiplied each into the strength of the current that flows through it, or the total change of potential around any closed circuit is zero.*

In applying Kirchhoff's laws the following rules should be observed: Currents flowing toward a junction should be preceded by a plus sign. Cur-

rents flowing away from a junction should be preceded by a minus sign. A rise in potential should be preceded by a plus sign. (This occurs in going

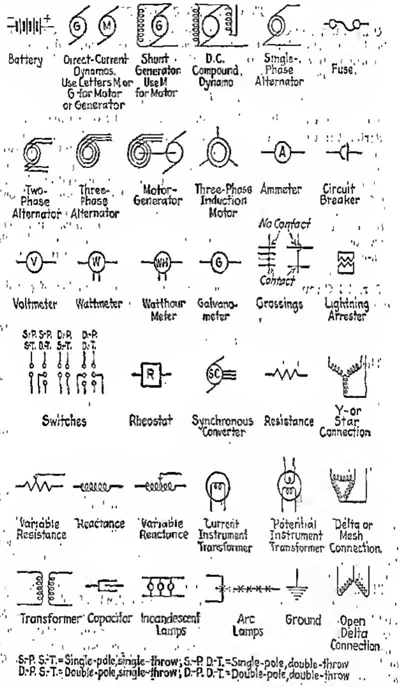

FIG. 2.—Diagrammatic Symbols for Electrical Machinery and Apparatus.

through a source of emf from the negative to the positive terminal, and in going through a resistance in opposition to the current flow.) A drop in

CONTENTS

potential should be preceded by a minus sign. (This occurs in going through a source of emf from the positive to the negative terminal and in going through a resistance in conjunction with the current flow.)

The application of Kirchhoff's laws is illustrated by the following example.

Example. Determine the three currents I_1, I_2, and I_3 in the circuit network (Fig. 3). The arrows show the assumed directions of the three currents.

Applying Kirchhoff's second law to circuit *a b c d e a*,

$$+4 + 0.2I_1 + 0.5I_1 - 3I_2 + 2 - 0.1I_2 + I_1 = 0$$

or,

$$+6 + 1.7I_1 - 3.1I_2 = 0 \qquad \text{(I)}$$

and for *e d c f g e*,

$$-2 + 0.1I_2 + 3I_2 + I_3 + 3 + 0.3I_3 = 0$$

or,

$$+1 + 3.1I_2 + 1.3I_3 = 0 \qquad \text{(II)}$$

Applying Kirchhoff's first law to junction *c*,

$$-I_1 - I_2 + I_3 = 0 \qquad \text{(III)}$$

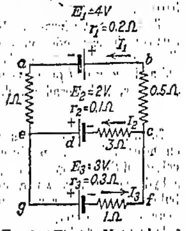

FIG. 3.—Electric Network and Kirchhoff's Laws.

Solving (I), (II), and (III) simultaneously gives $I_1 = -2.56$, $I_2 = +0.53$, and $I_3 = -2.03$. The minus signs before I_1 and I_3 show that the actual directions of flow of these two currents are opposite the assumed directions.

Electrical Power. With direct currents the electrical power is given by the product of the volts and amperes. That is, $P = EI$ **watts**. (14) Also, by substituting for E and I Eqs. (8) and (7), $P = I^2R$ watts (15); $P = E^2/R$ watts (16).

The practical unit of power is the **watt** $= 10^7$ ergs per sec. The watt is too small a unit for many purposes. Hence, the **kilowatt** (kw) (1,000 watts) is used. 746 watts $= 1$ hp. $= 0.746$ kw. 1 kw $= 1.340$ hp.

Joule's Law. When an electric current flows through a resistance, the number of heat units developed is proportional to the square of the current, directly proportional to the resistance, and directly proportional to the time that the current flows. $h = 0.2389i^2rt$, where h represents the number of IT gram-calories; i the current, amp; r the resistance, ohms; and t the time, sec. h (in Btu) $= 0.0009480i^2rt$. See p. 1689.

Electrical Energy. The fundamental unit of electrical energy is the erg. The practical unit is the **joule** or **watt-second** $= 10^7$ ergs. This unit is too small for most practical purposes, hence the **kilowatt-hour** (kwhr) is used.

BATTERIES

In an **electric cell** or **battery**, chemical energy is converted into electrical energy. Strictly speaking, the word battery applies to an assembly of cells, but the word has come to mean single units or cells. A battery is based on the fact that a potential difference exists between different elements. When two different elements are immersed in electrolyte an emf exists tending to send current within the cell from the negative pole, which is the more highly electropositive, to the positive pole. The poles or electrodes of a battery form the junction with the external circuit.

If the external circuit is closed, current flows from the battery at the *positive electrode* or *cathode*, and enters the battery at the *negative electrode* or *anode*.

MAGNETIC AND ELECTRICAL UNITS

Systems of Units. There are two fundamental systems of electrical units based dimensionally on the centimeter, gram, and second (cgs), the electrostatic and the electromagnetic. The cgs electrostatic system is derived from the force exerted between two unit charges of electricity at points 1 cm apart in a medium of unit dielectric constant. The cgs electromagnetic system is derived from the force exerted between two unit magnetic poles placed at points 1 cm apart in a medium of unit magnetic permeability. The practical units such as the volt and ampere are derived from the units of the electromagnetic system, differing from them only in their magnitudes.

The mks system has recently been adopted as a standard. It is based dimensionally on the meter, kilogram, and second. The electrical units are those of the practical system.

Magnetic calculations are usually made in the cgs electromagnetic system.

Unit magnetic pole is one that will repel an equal and like pole with a force of 1 dyne (see p. 1701) at a distance of 1 cm in a medium of unit permeability.

Magnetic potential is measured by the work involved in moving a unit magnet pole from the boundary of the field to the point at which the potential is desired.

Magnetic field intensity (H) is measured by the force in dynes exerted on a unit pole. In media whose permeability is unity the field intensity is given by the number of lines of force per square centimeter taken normal to their direction. The cgs unit of field intensity is the **oersted**.

Magnetic flux (Φ, ϕ) is the magnetic flow that exists in any magnetic circuit. The cgs unit is the **maxwell**.

Magnetic flux density (B) is the ratio of the flux in any cross section to the area of that cross section, the cross section being taken normal to the direction of flux. One maxwell per square centimeter is equal to 1 **gauss**.

Magnetomotive force ($\mathcal{F}$ and mmf) is that which tends to produce magnetic flux and corresponds to electromotive force in the electric circuit. The cgs unit is the **gilbert** which is equal to $0.4\pi nI$ where nI are the ampere-turns. The **ampere-turn** is frequently a convenient unit.

In a **primary battery** the chemically reacting parts require renewal; in a **secondary battery**, the electrochemical processes are reversible to a high degree and the chemically reacting parts are restored after partial or complete discharge by reversing the direction of current flow through the battery.

Electromotive force of a battery is the total potential difference existing between the electrodes on open circuit. When current flows, the potential difference across the terminals drops because of the resistance drop within the cell and because of **polarization.** If E is the emf of the cell, r the internal resistance, V the terminal voltage, when current I flows, then

$$V = E - Ir \tag{17}$$

Polarization. When current flows in a battery, hydrogen is deposited on the cathode. This produces two effects, both of which reduce the terminal voltage of the battery. The hydrogen in contact with the cathode constitutes a hydrogen battery which opposes the emf of the battery; the hydrogen bubbles reduce the contact area of the electrolyte with the cathode, thus increasing the battery resistance. The most satisfactory method of reducing polarization is to have present at the cathode some compound that supplies negative ions to combine with the positive hydrogen ions at the plate. In the Leclanché cell, manganese peroxide in contact with the carbon cathode serves as a depolarizer, its oxygen ion combining with the hydrogen ion to form water.

Primary Batteries

The **Leclanché** cell has carbon for the positive and zinc for the negative electrode with sal ammoniac as solution. It is used where only low values of current and intermittent service are desired. In the improved type the cathode is a porous carbon cup in which are packed lumps of manganese dioxide to serve as an insoluble oxidizing agent. The rather high internal resistance has been reduced by using a zinc cylinder for the anode and placing it about the carbon and as near as possible. The emf of this cell is about 1.4 volts, but the terminal voltage drops to approximately 1 volt when in service. This type of cell now is only of importance in that it forms the basis of the dry cell.

The **gravity cell** consists of a heavy zinc crowfoot as anode suspended on the top of a battery jar and a cathode of sheet copper in the bottom. The electrolytes are zinc sulphate about the anode and copper sulphate about the cathode. The two electrolytes are kept separate by gravity. This is a closed-circuit battery. The emf is about 1 volt.

The **Edison primary cell** has a cathode of copper oxide, an anode consisting of zinc plates, and an electrolyte of caustic soda ($NaOH$). The emf is about 0.9 volt and the terminal voltage is about 0.75 volt when in service. This battery can be used for either open- or closed-circuit work.

The foregoing primary batteries are practically obsolete so far as general use is concerned. They have been replaced by dry batteries, storage batteries, bell-ringing transformers, etc.

Dry Batteries. The dry battery is a development of the Leclanché battery and consists of a zinc container which serves as the negative electrode and is lined with specially prepared paper, or some similar absorbent material, to prevent the mixture of carbon and manganese dioxide, which is tamped tightly around the positive carbon electrode, from coming in contact with the zinc. The absorbent lining and the mixture are moistened with a solution of zinc chloride and sal ammoniac. In smaller cells the manganese-carbon mixture is often molded into a cylinder around the carbon electrode, the whole is then set into the zinc cup, and the space between the mold of mix and the zinc is filled with electrolyte made into a paste in such a manner that it can

between chord AB and the horizontal, F = area of cross-section, E = Young's modulus of elasticity (for steel, E = 29,000,000 lb per sq in.), l = stretched length (along curve).

If the tension P at the upper end is known, compute wL/P and find m from Table 6. Then $l = L + (LP/FE)(1 - m)$.

If the tension Q at the lower end is known, compute wL/Q and find n from Table 7. Then $l = L + (LQ/FE)(1 + n)$.

OTHER USEFUL CURVES

The Cycloid is traced by a point on the circumference of a circle which rolls without slipping along a straight line. **Equations of cycloid**, in parametric form (axes as in Fig. 65): $x = a$ (rad $u - \sin u$), $y = a(1 - \cos u)$, where a is

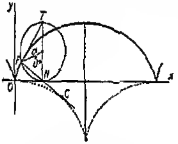

FIG. 65.

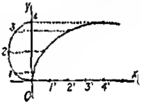

FIG. 66.

the radius of the rolling circle, and rad u is the radian measure of the angle u through which it has rolled. The tangent and normal at any point pass through the highest and lowest points of the corresponding position of the generating circle. The **radius of curvature** at any point P is $PC = 4a \sin(u/2) = 2\sqrt{2ay}$ = twice the length of the normal, PN. The **evolute**, or locus of centers of curvature, is an equal cycloid. ***To construct** a cycloid (Fig. 66)*, divide the semi-circumference of the generating circle into n equal parts (here 4) and lay off these arcs along the base (from O to $4'$). Describe arcs with centers at $1'$, $2'$, . . . and radii equal to the chords $O1$, $O2$, . . ., and sketch the cycloid as a curve tangent to all of these arcs. Or, on horizontal lines through 1, 2, . . . lay off distances equal to $O1'$, $O2'$, etc.; the points thus reached will lie on the cycloid.

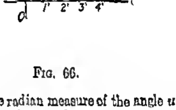

FIG. 67.

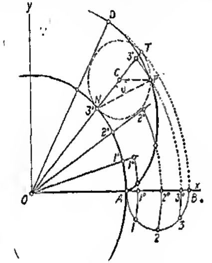
The area of one arch $= 3\pi a^2$, length of arc of one arch $= 8a$. Area bounded by the ordinate of the point P corresponding to any value of u is a^2 ($\frac{3}{2}$ rad $u - 2 \sin u + \frac{1}{4} \sin 2u) = \frac{3}{2} ax - \frac{1}{2} y\sqrt{(2a - y)y}$. Length of arc $OP = 4a (1 - \cos \frac{1}{2} u) = 4a - 2\sqrt{2a(2a - y)}$.

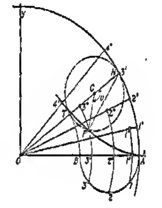
The Trochoid is a more general curve, traced by any point on a radiu of the rolling circle, at distance b from the center (Fig. 67). It is a prolat trochoid if $b < a$, and a curtate or looped trochoid if $b > a$. The equations ir either case are $x = a$ rad $u - b \sin u$, $y = a - b \cos u$.

The Epicycloid (or Hypocycloid) is a curve generated by a point on th circumference of a circle of radius a which rolls without slipping on th outside (or inside) of a fixed circle of radius c. For the **equations**, pu $b = a$ in the equations of the epi- (or hypo-) trochoid, below. The norma at any point P passes through the point of contact N of the correspondin position of the rolling circle. To construct the curve (Figs. 68 and 69)



Epicycloid.

FIG. 68.



Hypocycloid.

FIG. 69.

divide the semi-circumference of the rolling circle into n equal parts, by point 1, 2, 3 . . ., and lay off these arcs ($A1$, $A2$, $A3$) along the circumference of th base circle, as $A1'$, $A2'$, $A3'$, ... Describe circles with centers at 1′, 2′, 3′ . . . and radii equal to the chords $A1$, $A2$, $A3$, . . .; then the required curve will be tangent to all these circles. Or, with O as center, draw arc through 1, 2, 3, . . ., meeting the radius OA in 1^0, 2^0, 3^0, . . ., and th radii $O1'$, $O2'$, $O3'$, . . . in 1″, 2″, 3″, . . .; then from 1″, 2″, 3″, . . . lay off arcs equal to 1^01, 2^02, 3^03, . . . respectively; the points thu reached will be points of the curve.

The area $OAP = \dfrac{a(c \pm a)(c \pm 2a)}{2c}$ (rad $u - \sin u$), where the upper sig applies to the epicycloid, the lower to the hypocycloid, and rad u = th radian measure of the angle u shown in Figs. 68 and 69. Arc AP = $(4\,a/c)(c \pm a)(1 - \cos \tfrac{1}{2} u)$; arc $AD = (4a/c)(c \pm a)$. [In Fig. 69, $D = 4''$.

Radius of curvature at any point P is $R = \dfrac{4a(c \pm a)}{c \pm 2a} \sin \tfrac{1}{2}u$; at A, $R = 0$; at D, $R = \dfrac{4a(c \pm a)}{c \pm 2a}$.

Special Cases. If $a = \tfrac{1}{2}c$, the hypocycloid becomes a straight line, diameter of the fixed circle (Fig. 70). In this case the hypotrochoid traced by any

be solidified by either standing or heating. The emf of a dry cell when new is 1.4 to 1.6 volts.

In **block assembly** the dry cells, especially in the smaller sizes, are assembled in series and sealed in blocks of insulating compound with only two terminals and sometimes intermediate taps brought out. This type of battery is used for radio B and C batteries. Another construction is to build the battery up of layers in somewhat the manner of the old voltaic pile. Each cell consists of a layer of zinc, a layer of treated paper, and a flat cake of the manganese-carbon mixture. The cells are separated by layers of a special material which conducts electricity, but which is impervious to electrolyte. A sufficient number of such cells are built up to give the required voltage and the whole battery is sealed into the carton.

Dry cells and batteries fall generally into three classes: (1) the **large size dry cells** which are usually approximately 2½ in. diam by 6 in. height; (2) **flashlight batteries** which are of small size, usually 1¼ in. diam by 2¼ in. height or smaller; and (3) **radio B batteries** which consist usually of 15 or 30 cells permanently connected into a battery which is used chiefly to supply the B battery current for radio-receiving sets.

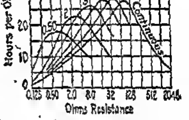


FIG. 4.—Service Efficiency Curves to Cut-off Voltage at Eight-tenths Volt for Various Periods of Discharge.

The **efficiency** of a standard-size dry battery depends on the rate at which it is discharged. Up to a certain rate the lower the discharge rate, the greater the efficiency. Above this rate the efficiency decreases. Figure 4 (*N.B.S. Circular 79*, p. 39) shows the service that may be obtained from an ordinary 6 in. dry cell. Thus, if a battery of dry cells is discharged through 16 ohms resistance for 15 min per hr to 0.8 volt, it will, from Fig. 4, give 28 hr of service per ohm. Since it is discharged through 16 ohms, the hours of service will be 448, and since it is on service 15 min per hr, the total life of the cell will be 1,792 hr, or about 75 days.

When used efficiently a 6 in. dry cell will give over 30 amp-hr of service. As ordinarily used, however, the dry cell gives no more than 8 to 10 amp-hr of service and at times even less. The 1¼ by 2¼ in. flashlight battery is usually employed with a lamp taking 0.25 to 0.35 amp. Under these conditions 3 amp-hr or thereabouts may be expected if the battery is used for not more than an hour or so a day. The so-called "heavy-duty" radio battery will give about 8 to 10 amp-hr when efficiently used.

For the best results 6 in. dry cells should not be used for current drains of over 0.5 amp except for very short periods of time. Flashlights should not be used for higher than the preceding current drain, and heavy-duty radio batteries will give best results if the current drain is kept below 25 milliamp.

Dry cells should be stored in a cool, dry place. Extreme heat during storage will shorten their life. The cell will not be injured by being frozen but will be as good as new after being brought back to normal temperature. In extreme cold weather dry cells may not give more than half of their normal service. At a temperature of about −30 they freeze solid and give neither voltage nor current.

The amperage of a dry cell by definition is the current that it will give when it is short-circuited through an ammeter which with its leads has a resistance of 0.01 ohm. For correct results, the amperage of a dry cell must be taken at about 70 F.

The **Weston cell** is a primary cell used as a standard of emf. It consists of a glass H-tube in the bottom of one leg of which is mercury which *forms* the positive or cathode; in the bottom of the other leg is cadmium amalgam forming the anode. The electrolytes consist of mercurous sulphate and cadmium sulphate. The emf of the unsaturated, or working, cell is approximately 1.0186 volts. The saturated cell can be reproduced to 2 or 3 parts in 100,000 and hence is a very accurate standard. No appreciable current

Equations (32) and (33) are used for calculating the capacitance of overhead transmission lines. When computing charging current, use voltage between lines in (32) and to neutral in (33).

Capacitances in Parallel. The equivalent capacitance of capacitances in parallel (Fig. 17)

$$C = C_1 + C_2 + C_3 \tag{34}$$

Capacitances in parallel are all across the same voltage. If the voltage is E, then the total quantity $Q = CE$ and $Q_1 = C_1E$, etc.

Capacitances in Series. The equivalent capacitance C of capacitances in series (Fig. 18) is found as follows:

$$1/C = 1/C_1 + 1/C_2 + 1/C_3 \tag{35}$$

If the capacitances are not leaky, the charge Q is the same on each. $Q = CE$, $E_1 = Q/C_1$, $E_2 = Q/C_2$, etc.

Insulators and Dielectrics. Insulating materials are applied to electric circuits to prevent the leakage of current. Insulating materials when used with high voltage must not only have a high resistance to leakage current, but must also be able to resist dielectric puncture. That is, in addition to being a good insulator, the material must be a good dielectric. Insulation resistance is usually expressed in megohms (10^6 ohms) and the resistivity given in megohms per centimeter cube. The dielectric strength is usually given in terms of voltage gradient, common units being volts per mil, volts per millimeter, and kilovolts per centimeter. Insulation resistance decreases very rapidly with increase in temperature. Absorbed moisture reduces the insulation resistance, and moisture and humidity have a large effect on surface leakage.

Transients

Induced EMF. If a flux ϕ linking n turns of conductor changes, an emf

$$e = -n(d\phi/dt)10^{-8} \text{ volts} \tag{36}$$

is induced.

Self-inductance. Let a flux ϕ link n turns. The linkages of the circuit are $n\phi$ maxwell-turns. If the permeability of the circuit is assumed constant, then the number of these linkages per ampere ($\times 10^{-8}$) is the **self-inductance** or **inductance** of the circuit. The unit of inductance is the **henry**. The inductance is

$$L = n\phi/(i \times 10^8) \text{ henrys} \tag{37}$$

If the permeability changes with the current

$$L = n(d\phi/di)10^{-8} \text{ henrys} \tag{38}$$

The energy stored in the magnetic field

$$W = \tfrac{1}{2}Li^2 \text{ joules} \tag{39}$$

EMF of Self-induction. If Eq. (37) be written $Li = n\phi 10^{-8}$ and differentiated with respect to the time t, $L(di/dt) = n(d\phi/dt)10^{-8}$ and from Eq. (36)

$$e = -L(di/dt) \text{ volts} \tag{40}$$

This is the emf of self-induction. In a circuit, if a rate of change of current of 1 amp per sec induces an emf of 1 volt, the inductance is 1 henry.

Current in Inductive Circuit. If a circuit containing resistance R and inductance L in series is connected across a steady voltage E, the voltage E must supply the iR drop in the circuit and at the same time overcome the emf

can be taken from the cell, hence some null method must be used to utilize its emf (see p. 1997).

Storage Batteries

In a **storage battery** the electrolytic action must be **reversible**. There are two types of storage batteries, the lead-lead-acid type and the nickel-iron-alkaline type (Edison battery).

In the manufacture of the **lead-lead-acid cells** there are two general types of plates or electrodes. In the **Planté type** the active material is electrically formed of pure lead by repeated reversals of the charging current. In the **Faure or pasted plate** the active material is obtained by applying paste to supporting grids, lead peroxide to the positive and lead oxide to the negative plate.

In order to obtain high capacity per unit weight it is necessary to expose a large plate area to the action of the acid. This is done in the Planté plate by ploughing with sharp steel disks and by using corrugated helical inserts as active positive material (Manchester plate). In the pasted plate a large area of the material is necessarily exposed to the action of the acid.

The chemical reactions in a lead cell may be expressed by the following equation, based on the double sulphation theory:

$$\underset{\substack{\text{Positive}\\\text{plate}}}{PbO_2} + \underset{\substack{\text{Negative}\\\text{plate}}}{Pb} + \underset{\substack{\text{Sulphuric}\\\text{acid}}}{2H_2SO_4} \underset{\text{Discharge}}{\overset{\text{Charge}}{\rightleftharpoons}} \underset{\substack{\text{Positive and}\\\text{negative plates}}}{2PbSO_4} + \underset{\text{water}}{2H_2O}$$

Between the extremes of complete charge and discharge, complex combinations of lead and sulphate are formed. After complete discharge a hard insoluble sulphate forms slowly on the plates, and this is reducible only by slow charging. This sulphation is objectionable and should be avoided.

Specific Gravity. Water is formed with discharge, and sulphuric acid is formed on charge, consequently the specific gravity must decrease on discharge and increase on charge. The variation of the specific gravity for a stationary battery is shown in Fig. 5. With starting and vehicle batteries it is necessary to operate the electrolyte from between 1.280 to 1.300 when fully charged to as low as 1.100 when completely discharged. The condition of charge of a battery may be determined by its specific gravity.

FIG. 5.—Variations of Specific Gravity in a Stationary Battery.

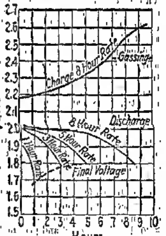

FIG. 6.—Voltage Curves on Charge and Discharge for Lead Cell.

of self-induction. That is $E = Ri + Ldi/dt$. A solution of the differential equation gives

$$i = (E/R)(1 - \epsilon^{-Rt/L}) \text{ amp} \tag{41}$$

where ϵ is the base of the natural system of logarithms.

Figure 19 shows this equation plotted when $I_0 = 0.5$ amp, $R = 20\Omega$, $L = 0.6$ henry. It is to be noted that inductance causes the current to rise slowly to its Ohm's law value. When $t = L/R$, the current has reached 63.2 percent of its Ohm's law value. L/R is the **time constant** of the circuit.

If a circuit containing inductance and resistance in series be short-circuited when the current is I_0, the equation of current becomes

$$i = I_0\epsilon^{-Rt/L} \text{ amp} \tag{42}$$

Figure 20 shows this equation plotted when $I_0 = 0.5$ amp, $R = 20\Omega$, $L = 0.6$ henry. It is seen that inductance opposes the decay of current. Inductance always opposes change of current.

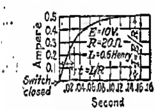

FIG. 19.—Rise of Current in Inductive Circuit

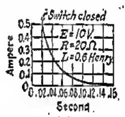

FIG. 20.—Decay of Current in Inductive Circuit.

Mutual Inductance. If two circuits are so related to each other geometrically that any portion of the flux produced by the current in one circuit links the other circuit, the two circuits possess *mutual inductance*. It follows that a change of current in one circuit causes an emf to be induced in the other. Let e_2 be induced in circuit 2 by a change di_1/dt in circuit 1. Then

$$e_2 = Mdi_1/dt \text{ volts} \tag{43}$$

M is the mutual inductance of the two circuits. Also a change of current di_2/dt in circuit 2 induces an emf e_1 in circuit 1, $e_1 = Mdi_2/dt$.

Current in Capacitive Circuit. If a capacitance C farads and a resistance R ohms be connected in series across the steady voltage E, the current

$$i = (E/R)\epsilon^{-t/CR} \text{ amp} \tag{44}$$

If a capacitor charged to voltage E be discharged through resistance R, the current

$$i = -(E/R)\epsilon^{-t/CR} \text{ amp} \tag{45}$$

Except for sign, these two equations are identical and are of the same form as (42).

Resistance, Inductance, and Capacitance in Series. If a circuit having resistance, inductance, and capacitance in series is connected across a source of steady voltage a transient condition results. If $R > \sqrt{4L/C}$ or $R = \sqrt{4L/C}$ the transient dies out rapidly without oscillation. The value of $R = \sqrt{4L/C}$ is the **critical damping resistance.** If $R < \sqrt{4L/C}$ the transient oscillates at a frequency equal very nearly to $1/(2\pi\sqrt{LC})$. If a capacitor is discharged into resistance and inductance in series, these same conditions exist.

Battery electrolyte may he made from concentrated sulphuric acid (oil of vitriol, sp gr 1.84) by *pouring the acid into the water* in the following proportions.

Table 5. Parts Water to One Part Acid

Specific gravity	1.200	1.210	1.240	1.280
Volume	4.3	4.0	3.4	2.75
Weight	2.4	2.2	1.9	1.5

Table 6. Freezing Temperatures of Sulphuric Acid

Specific gravity	1.180	1.200	1.240	1.280
Freezing temp, F	−6	−16	−51	−90

Voltage. The emf of a lead cell when fully charged and idle is 2.05 to 2.10 volts. Discharge lowers the voltage in proportion to the current flowing. Complete *discharge* is reached at 1.7 volts. When *charging* at constant current and normal rate, the terminal voltage gradually increases from 2.2 to 2.35 volts, then increases rapidly to between 2.5 and 2.7 volts (Fig. 6). This latter interval is known as the *gassing period*. When this period is reached, the charging rate should be reduced in order to avoid waste of power and unnecessary deterioration of the plates.

Practically all batteries have a **normal rating** based on the 8-hr rate of discharge. Thus a 320 amp-hr battery would have a normal rate of 40 amp. The amp-hr capacity of batteries falls off rapidly with increase in discharge rate.

Table 7. Effect of Discharge Rate on Battery Capacity

Discharge rate, hr	8	5	3	1	$\frac{1}{3}$	$\frac{1}{10}$
Percentage of rated capacity. Planté type	100	88	75	55.8	37	19.5
Percentage of rated capacity. Pasted type	100	93	83	63	41	25.5

The following rule may be observed in **charging a lead battery:** The charging rate in amp may always be made equal to the number of amp-hr out of the battery. For example, if 200 amp-hr are out of a battery, a charging rate of 200 amp may be used until the amp-hr out of the battery are reduced appreciably.

There are two common methods of charging, the **constant-current** method and the **constant-potential method.** Figure 7 shows a common method of charging with constant current, the battery being in series with resistance across d-c mains. Several batteries may be connected in series. If the polarity of the two wires is not known, it may be determined by placing them in a container of salty water; the negative wire will generate gas more freely than the other. By moistening a strip of litmus paper with salty water and holding the wires from the charging system close together on this strip of paper, an acid reaction develops a red spot under the positive terminal and an alkaline reaction produces a blue spot under the negative.

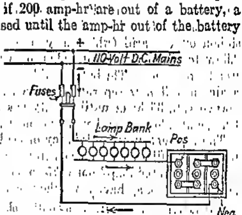

FIG. 7.—Charging a Starting Battery from 110-volt Mains.

The constant-potential method is to be preferred, since the rate automatically tapers off as the cell approaches the charged condition. Without resistance the terminal voltage should be 2.3 volts per cell, but it is preferable to use 2.4 to 2.5 volts per cell with a low resistance in series.

ALTERNATING CURRENTS

Sine Waves. In the following discussion of alternating currents sine waves of voltage and current will be assumed. That is, $e = E_m \sin \omega t$ and $i = I_m \sin (\omega t - \theta)$ where E_m and I_m are maximum values of voltage and current; ω, the angular velocity in radians per second, is equal to $2\pi f$ where f is the frequency; and θ is the angle of phase difference.

Cycle; Frequency. When any given armature coil has passed a pair of poles, the emf or current has gone through 360 electrical degrees or 1 cycle. An alternation is one-half a cycle. The frequency of an alternator in cycles per second

$$f = NP/120 \tag{46}$$

where N is the speed in rpm and P the number of poles. Standard frequencies are 60 cycles for lighting and power and 25 cycles for power. Frequencies of 40 and 50 cycles are used in some localities, and 12½ and 15 cycles are used abroad in railway work. One hundred and thirty-three cycles was extensively used some years ago but is rarely used at the present time.

The effective value of a wave (root-mean-square value) produces the same heating in a given resistance as a direct current of the same value. Since the heating effect of a current is proportional to i^2r, the effective value is obtained by squaring the ordinates, finding their average value, and extracting the square root, i.e., the effective value

$$I = \sqrt{1/T \int_0^T i^2 dt} \text{ amp}$$

where T is the time of a cycle. The effective value I of a sine wave equals $(1/\sqrt{2})I_m = 0.707I_m$.

The Average Value of a Wave. The average value of a sine wave over a complete cycle is zero. For a half-cycle the average is $(2/\pi)I_m$, or $0.637\ I_m$, where I_m is the maximum value of the sine wave. The average value is of little practical importance. A d-c measuring instrument gives the average values of a pulsating wave. The average value is of use only when the effects of the current are proportional to the number of coulombs passing, as in electrolytic work.

Form Factor. The form factor of a wave is the ratio of effective value to average value. For a sine wave this is $\pi/(2\sqrt{2}) = 1.11$. This factor is important in that it enters equations for induced emf.

Inductive reactance, $2\pi fL$ or ωL, opposes an alternating current in passing through an inductance L. It is expressed in ohms. Reactance is usually denoted by the symbol X. Inductive reactance is denoted by X_L.

The current through an inductive reactance X_L when connected across the voltage E is

$$I = E/X_L = E/(2\pi fL) \text{ amp} \tag{47}$$

This current lags the voltage by 90 deg. Inductance absorbs no energy. The energy stored in the magnetic field during each half-cycle is returned to the source during the same half-cycle.

Capacitive reactance is $1/(2\pi fC) = 1/\omega C$ and is denoted by X_C, where C is in *farads*. If C is given in microfarads, $X_C = 10^6/2\pi fC$. The current through a capacitive reactance X_C when connected across voltage E is

$$I = E/X_C = 2\pi fCE \text{ amp} \tag{48}$$

This current leads the voltage by 90 deg. Capacitance absorbs no energy.

When a battery is being charged, its terminal voltage $V = E + Ir$. (18) Compare with Eq. (17).

When a battery is fully charged, any rate will produce gassing, but the rate may be reduced to such a low value that gassing is practically harmless. This is called the **finishing rate.**

Stationary Batteries. The containing tanks are glass jars in the smaller sizes and lead-lined wooden tanks in the large sizes. The lead must be burned, not soldered, and the wood painted with asphaltum or other acid-resisting paint. When batteries are to be used for **regulating duty**, Planté positive plates should be used because of their long life. When used for **stand-by service**, pasted positive plates should be used because of their high rate of discharge. This is the more common use of batteries in central-station service. Pasted negatives are used in practically all stationary batteries. The separators are of thin wood veneer.

Because of the necessity of having very high discharge rates for their size and weight, **starting and lighting batteries** employ pasted plates. The separators may be wood veneer alone, or in the better types the wood may be reinforced with perforated hard rubber. The Electric Storage Battery Co. has developed a sheet-rubber separator having microscopic pores, hence the name "mipor." Also "fiberglas" fabric, woven from spun-glass fibers, is being used for separators. The jars are made of hard rubber sealed with asphaltum.

The **Exide Ironclad** battery is designed for propelling electric vehicles. The positive plate consists of a lead-antimony frame supporting perforated hard-rubber tubes. An irregular lead-antimony core runs down the center of each tube, and the lead peroxide paste is packed into these tubes so that shedding of active material from the positive plate cannot occur. Pasted negative plates are used.

A storage battery **removed from service** for less than 9 months should be charged once a month if possible, but if not, it should be given a heavy overcharge before discontinuing service. If removed for a longer period, siphon off the acid (which may be used again) and fill with fresh water. Allow to stand 15 hr and siphon off water. Remove and throw away the wood separators. The battery will now stand indefinitely. To put in service again, install new separators, fill with acid (sp gr 1.210), and charge at normal rate 35 hr or until gravity has ceased to rise over a period of 5 hr. Charge at a low rate a few hours longer.

The **ampere-hour efficiency** of lead batteries is 90 to 95 percent. The **watthour efficiency** obtained from full charge to discharge at the normal rate and at rated amp-hour is 75 to 85 percent. Batteries which do regulating duty only may have a watthour efficiency as high as 95 percent.

The **Edison storage cell** has a positive plate of nickel pencils filled with green nickel oxide and a negative plate of flat nickel-plated steel stampings containing iron in finely divided form. The active material for the positive plate is nickel hydrate and for the negative plate iron oxide. The electrolyte is a 21 percent solution of potassium hydrate with a little lithium hydrate. The initial emf is about 1.5 volts and the average emf about 1.1 volts throughout discharge. On account of the high internal resistance of the cell the battery is not efficient from the energy standpoint, 60 percent being the efficiency usually attained in practice. The jar is welded nickel-plated steel. The battery is compact and extremely light and strong and, for these reasons, is particularly adapted for propelling electric vehicles and for train-lighting systems.

Precautions in the **care of storage batteries**: An ammeter should not be connected directly across the terminals to test the condition of a cell; a battery should not be left to stand in a discharged condition; a flame should not be brought in the vicinity of a

The energy stored in the dielectric field during each half-cycle is returned to the source during the same half-cycle.

Impedance opposes the flow of alternating current and is expressed in ohms. It is denoted by Z. With resistance and inductance in series

$$Z = \sqrt{R^2 + X_L^2} = \sqrt{R^2 + (2\pi fL)^2} \text{ ohms} \tag{49}$$

With resistance and capacitance in series

$$Z = \sqrt{R^2 + X_C^2} = \sqrt{R^2 + [1/(2\pi fC)]^2} \text{ ohms} \tag{50}$$

With resistance, inductance, and capacitance in series

$$Z = \sqrt{R^2 + (X_L - X_C)^2} = \sqrt{R^2 + [2\pi fL - 1/(2\pi fC)]^2} \text{ ohms} \tag{51}$$

The current

$$I = E/\sqrt{R^2 + [2\pi fL - 1/(2\pi fC)]^2} \text{ amp} \tag{52}$$

Vector Representation. Sine waves of voltage and current can be represented by vectors, these vectors being proportional in magnitude to the waves that they represent. The angle between two vectors is also equal to the angle existing between the two waves that they represent.

Vectors may be combined as forces are combined in mechanics. Both graphical methods and the methods of complex algebra are used. Impedances and also admittances may be similarly combined, either graphically or symbolically. The usual method is to resolve the impedances into their component resistances and reactances, then combine all resistances and all reactances, from which the resultant impedance is obtained. Thus $Z_1 + Z_2 = \sqrt{(r_1 + r_2)^2 + (x_1 + x_2)^2}$, where r_1 and x_1 are the components of Z_1, etc.

Phase Difference. With resistance only in circuit the current and the voltage are in phase with each other; with inductance only in circuit the current lags the voltage by 90 deg; with capacitance only in circuit the current leads the voltage by 90 deg.

With resistance and inductance in series the voltage leads the current by angle θ where $\tan\theta = X_L/R$. With resistance and capacitance in series the voltage lags the current by angle θ where $\tan\theta = -X_C/R$.

With resistance, inductance, and capacitance in series the voltage may lag, lead, or be in phase with the current.

$$\operatorname{Tan}\theta = (X_L - X_c)/R = (2\pi fL - 1/2\pi fC)/R \tag{53}$$

If $X_L > X_c$, the voltage leads; if $X_L < X_c$, the voltage lags; if $X_L = X_c$, the current and voltage are in phase.

Power Factor. In a-c circuits the power $P = I^2R$ where I is the current and R the effective resistance (p. 1711). Also the power

$$P = EI\cos\theta \text{ watts} \tag{54}$$

where θ is the phase angle between E and I. Cos θ is the **power factor** (p.f.) of the circuit. It can never exceed unity and is usually less than unity.

$$\cos\theta = P/EI \tag{55}$$

P is often called the true power. The product EI is the volt-amp and is often called the apparent power.

Active or **energy current** is the projection of the total current on the voltage vector. $I_e = I\cos\theta$. Power $= EI_e$.

battery that is being charged; the battery should not be allowed to become heated when charging; water should never be added to the concentrated acid—always acid to the water; acid should never be equalized except when the battery is in a charged condition; a battery should never be exposed to the influence of external heat; voltmeter tests should be made when the current is flowing; batteries should always be kept clean. To replace acid lost through slopping, use a solution of 2 parts concentrated sulphuric acid in 5 parts water by weight, unless a hydrometer is at hand to enable the solution to be made up according to the specifications of the makers of the cell.

MAGNETISM

The Magnetic Circuit. The magnetic circuit is analogous to the electric circuit in that the flux Φ is proportional to the magnetomotive force ($\mathfrak{F}$) and inversely proportional to the reluctance ($\mathfrak{R}$) or magnetic resistance. Thus $\Phi = \mathfrak{F}/\mathfrak{R}$ (19). [Compare with Eq. (9), p. 1693.] Φ is in maxwells, $\mathfrak{F}$ in gilberts, and $\mathfrak{R}$ in cgs reluctance units.

Table 8. Magnetic Units

Symbol	*Quantity*	*Equation*[a]	*Practical unit*
m	Pole strength	$\mathfrak{F}/\mathfrak{R}$	
H	Field intensity	$H = F/m$	Oersted or dynes per cm
Φ, ϕ	Flux	$\Phi = \mu HA$	Maxwell
B	Flux density	$B = \Phi/AI$	Gauss
H	Magnetizing force	$H = 4\pi nI/10L$	Gilberts per cm
$\mathfrak{F}$	Magnetomotive force	$\mathfrak{F} = 4\pi nI/10$	Gilberts
ν	Reluctivity	$\nu = 1/\mu$	
$\mathfrak{R}$	Reluctance	$\mathfrak{R} = \nu L/A = \mathfrak{F}/\Phi$	
μ	Permeability	$\mu = \mathfrak{B}/H$	
$\mathcal{P}$	Permeance	$\mathcal{P} = 1/\mathfrak{R}$	

[a] L = length; A = sectional area; F = force, dynes; n = number of turns.

The magnetic path is large in cross section as compared with its length; magnetic paths are usually irregular and geometrically indeterminate as in air gaps having slots and teeth on one or both sides of the gap. Hence the reluctance can only be approximated. Magnetic flux cannot be confined to definite magnetic paths, but a considerable proportion usually takes paths external to the circuit giving magnetic leakage (see Fig. 10). The permeability of iron varies over wide ranges with the flux density and with the previous magnetic condition. These variations of permeability cannot be expressed by any simple equation. The foregoing factors prevent the obtaining of the high accuracy in magnetic calculations that is obtainable in electrical calculations, but with experience it is possible to design magnetic circuits with a very fair degree of accuracy.

The **magnetomotive force** $\mathfrak{F}$ in Eq. (19) is expressed in gilberts $= 0.4\pi nI$ where n is the number of turns linked with the circuit and I is the current in amp. The unit of reluctance is the reluctance of 1 cm cube of air. The total reluctance is proportional to the length and inversely proportional to the cross-sectional area of the magnetic circuit, which is analogous to electrical resistance. Hence the reluctance of any given path of uniform cross section A is $l/A\mu$ where l is the length of the path in cm, A its cross section in sq cm, and μ is the permeability. Reluctances in series are added to obtain their combined reluctance. Ohm's law of the magnetic circuit becomes

$$\Phi = \frac{0.4\pi nI}{l_1/A_1\mu_1 + l_2/A_2\mu_2 + l_3/A_3\mu_3 \ldots} \qquad (20)$$

Reactive, quadrature, or wattless current $I_w = I \sin \theta$ and is the component of the current that contributes no power but increases the I^2R losses of the system. In power systems it should be made as low as possible or eliminated entirely.

The vars (volt-amp reactive) are equal to the product of the voltage and reactive current. Vars $= EI_w$. Kilovars $= EI_w/1{,}000$.

Effective Resistance. When alternating current flows in a circuit, the losses are ordinarily greater than are given by the losses in the ohmic resistance alone. For example, alternating current tends to flow near the surface of conductors (skin effect). If iron is associated with the circuit, eddy current and hysteresis losses result. These power losses may be accounted for by increasing the ohmic resistance to a value R, where R is the effective resistance. $R = P/I^2$. Since the iron losses vary as $I^{1.6}$ to I^2, little error results from this assumption.

Solution of Series-circuit Problem. Let a resistance R of 10 ohms, an inductance L of 0.06 henry, and a capacitance C of 60×10^{-6} farad be connected in series across 120-volt 60-cycle mains (Fig. 21). Determine: (1) the impedance; (2) the current; (3) the voltage across the resistance, the inductance, the capacitance; (4) the power factor; (5) the power; (6) the angle of phase difference.

(1) $\omega = 2\pi 60 = 377$. $X_L = 0.06 \times 377 = 22.6\Omega$; $X_c = 1/(377 \times 0.000060) = 44.2\Omega$; $Z = \sqrt{(10)^2 + (22.6 - 44.2)^2} = 23.8\Omega$; (2) $I = 120/23.8 = 5.04$ amp.; (3) $E_R = IR = 5.04 \times 10 = 50.4$ volts; $E_L = IX_L = 5.04 \times 22.6 = 114.0$ volts; $E_c = IX_c = 5.04 \times 44.2 = 223$ volts; (4) $\tan \theta = (X_L - X_c)/R = -21.6/10 = -2.16$, $\theta = -65.2°$, $\cos = \text{p.f.} = 0.420$; (5) $P = 120 \times 5.04 \times 0.420 = 254$ watts; $P = I^2R = (5.04)^2 10 = 254$ watts (check); (6) From (4) $\theta = -65.2°$. Voltage lags. The vector diagram to scale of this circuit is shown in Fig. 22. Since the current is common for all elements of the circuit, it is laid horizontally along the axis of reference.

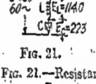

FIG. 21.

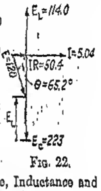

FIG. 22.

FIG. 21.—Resistance, Inductance and Capacitance in Series.

FIG. 22.—Vector Diagram for Series Circuit.

Resonance. If the voltage E and the resistance R [Eq. (52)] are fixed, the maximum value of current occurs when $2\pi fL - 1/2\pi fC = 0$. The circuit so far as its terminals are concerned behaves like a non-inductive resistance. The current $I = E/R$, the power $P = EI$, and the power factor is unity.

The voltage across the inductance and the voltage across the capacitance are opposite and equal and may be many times greater than the circuit voltage. The frequency

$$f = 1/(2\pi\sqrt{LC}) \text{ cycles} \tag{56}$$

is the natural frequency of the circuit and is the frequency at which it will oscillate if the circuit is not acted upon by some external frequency (p. 1984). This is the principle of radio sending and receiving circuits. Resonant conditions of this type should be avoided in power circuits, as the piling up of voltage may endanger apparatus and insulation.

Example. For what value of the inductance in the circuit (Fig. 21) will the circuit be in resonance, and what is the voltage across the inductance and capacitance under these conditions?

From Eq. (56) $L = 1/(2\pi f)^2C = 0.1173$ henry. $I = E/R = 120/10 = 12$ amp. $L\omega I = I/C\omega = 0.1173 \times 377 \times 12 = 530$ volts. This voltage is over four times the line voltage.

where l_1, A_1, μ_1, etc., are the lengths, cross sections, and permeabilities of each series part of the circuit.

Magnetization and Permeability Curves. The magnetic permeability of air is a constant and is taken as unity. The permeability of iron and other magnetic substances varies with the flux density. A curve of permeability as a function of flux density for cast steel is shown in Fig. 8. No satisfactory equation has been found to express the relation between magnetizing force and flux density and between permeability and flux density. Hence, if an attempt is made to solve Eq. (20) for flux, the factors μ_1, μ_2, etc., are unknown since they are functions of the flux density, which is being determined. The simplest method is one of trial and error, i.e., a value of flux, and the corresponding permeability, is first assumed; the equation solved for the flux, and if the computed flux differs widely from the assumed flux, a second approximation is made, etc. Fortunately, in nearly all magnetic designs either the flux or flux density is the independent variable, and it is required to find the necessary amp-turns to produce them. Let the flux $\Phi = BA$ where B is the flux density. Then

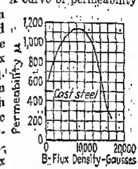

FIG. 8.—Permeability Characteristic of Cast Steel.

$$\Phi = BA = 0.4\pi nI/(l/A\mu)$$

and

$$nI = Bl/0.4\pi\mu = 0.796Bl/\mu \tag{21}$$

Eq. (21) shows that the necessary amp-turns are proportional to the *flux density* and the length of path and are inversely proportional to the permeability.

With air and non-magnetic substances μ [Eq. (21)] becomes unity and

$$nI = 0.796Bl \tag{22}$$

in centimeter units. With inch units

$$nI = 0.313B'l' \tag{23}$$

where B' is the flux density in lines per sq in. and l' the length of the magnetic path in inches.

Example. The average flux density in the air gap of a generator is 40,000 lines per sq in., and the effective length of the gap is 0.2 in. How many ampere-turns per pole are necessary for the gap?

$$nI = 0.313 \times 40{,}000 \times 0.2 = 2{,}500$$

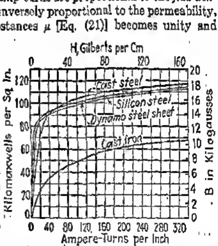

FIG. 9.—Typical Magnetization Curves.

Since the relation of μ to flux density in Eq. (21) is not simple, the relation of ampere-turns per unit length of magnetic circuit to flux density is ordinarily shown graphically. Typical curves of this character are shown in Fig. 9, inch units being used although scales of kilogausses and gilberts per cm are also given. To find the kilolines per sq cm (kilogausses), divide the ordinate scale by 6.45. To determine the number of ampere-turns necessary to produce a given total flux in a magnetic circuit composed of several parts in series having

Parallel Circuits

Parallel circuits are used for nearly all power distribution. With several series circuits in parallel it is merely necessary to find the current in each and add all the currents vectorially to find the total current. Parallel circuits may be solved analytically.

A series circuit has a resistance r_1 and an **inductive reactance** x_1. The **conductance**

$$g_1 = r_1/(r_1^2 + x_1^2) = r_1/Z_1^2 \text{ mhos} \tag{57}$$

the **susceptance**

$$b_1 = x_1/(r_1^2 + x_1^2) = x_1/Z_1^2 \text{ mhos} \tag{58}$$

Conductance is not the reciprocal of resistance; susceptance is not the reciprocal of reactance. With inductive reactance the susceptance is negative; with capacitive reactance the susceptance is positive.

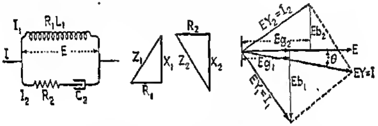

FIG. 23.—Parallel Circuit and Vector Diagram.

If a second circuit has a resistance r_2 and a **capacitive reactance** x_2 in series, $g_2 = r_2/(r_2^2 + x_2^2) = r_2/Z_2^2$; $b_2 = x_2/(r_2^2 + x_2^2) = x_2/Z_2^2$. The total conductance $G = g_1 + g_2$; the total susceptance $B = -b_1 + b_2$. The **admittance**

$$Y = \sqrt{G^2 + B^2} = 1/Z \text{ mhos} \tag{59}$$

The energy current is EG; the reactive current is EB; the power

$$P = E^2G \text{ watts} \tag{60}$$

The power factor

$$\text{p.f.} = G/Y \tag{61}$$

Also the following relations hold:

$$r = g/(g^2 + b^2) = g/Y^2 \text{ ohms} \tag{62}$$

$$x = b/(g^2 + b^2) = b/Y^2 \text{ ohms} \tag{63}$$

Solution of a Parallel-circuit Problem. In the parallel circuit of Fig. 23 it is desired to find the joint impedance, the total current, the power in each branch, the total power and the power factor, when $E = 100$, $f = 60$, $R_1 = 2$ ohms, $R_2 = 4$ ohms, $L_1 = 0.00795$ henry, $X_1 = 2\pi fL_1 = 3$ ohms, $C_2 = 1{,}326 \times 10^{-6}$ farad, $X_2 = 1/2\pi fC_2 = 2$ ohms, $Z_1 = \sqrt{2^2 + 3^2} = 3.6$ ohms, and $Y_1 = 1/3.6 = 0.278$ mho. Solution: $g_1 = R_1/(R_1^2 + X_1^2) = 2/13 = 0.154$; $b_1 = -3/13 = -0.231$; $Z_2 = \sqrt{16 + 4} = 4.47$; $Y_2 = 1/4.47 = 0.224$; $g_2 = R_2/(R_2^2 + X_2^2) = 4/(16 + 4) = 0.2$; $b_2 = 2/20 = 0.1$ mho; $G = g_1 + g_2 = 0.154 + 0.2 = 0.354$ mho; $B = b_1 + b_2 = -0.231 + 0.1 = -0.131$ mho; $Y = \sqrt{G^2 + B^2} = \sqrt{0.354^2 + (-0.131)^2} = 0.377$ mho, and joint impedance $Z = 1/0.377 = 2.65$ ohms. Phase angle $\theta = \tan^{-1}\dfrac{-0.131}{0.354} = -20.3°$. $I = EY = 100 \times 0.377 = 37.7$ amp; $P_1 = E^2g_1 = 100^2 \times 0.154 = 1{,}540$ watts; $P_2 = E^2g_2 = 100^2 \times 0.2 = 2{,}000$ watts; total power $= E^2G = 100^2 \times 0.354 = 3{,}540$ watts. Power factor $= \cos\theta = \dfrac{3{,}540}{100 \times 37.7} = 93.8$ percent.

various lengths, cross sections, and permeabilities, determine the flux density if the cross section is fixed, or otherwise choose a cross section to give a suitable flux density. From the magnetization curve obtain the ampere-turns necessary to drive this *flux density* through a unit length of the portion of the circuit considered and multiply by the length. Add together the ampere-turns required for each series part of the magnetic circuit to obtain the total ampere-turns necessary to give the assumed flux.

It is desirable to operate magnetic circuits at as high flux densities as is practicable in order to reduce the amount of iron and copper. The air gaps of dynamos are operated at average densities of 40,000 to 50,000 lines per sq in. Higher densities increase the exciting ampere-turns and tooth losses. At 45,000 lines per sq in. the flux density in the teeth may be as high as 120,000 to 130,000 lines per sq in. The flux densities in transformer cores are limited as a rule by the permissible losses. At 60 cycles and with silicon steel the maximum density is 60,000 to 70,000 lines per sq in.; at 25 cycles the density may run as high as 70,000 to 80,000 lines per sq in. With laminated cores, the *net* iron is approximately 0.9 the gross cross section.

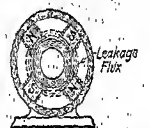

FIG. 10.—Magnetic Circuit of 4-pole Dynamo Showing Leakage Flux.

Magnetic Leakage. It is impossible to confine all magnetic lines to any desired path since there is no known insulator of magnetic lines. Figure 10 shows the magnetic circuit of a modern four-pole dynamo. A considerable proportion of the useful magnetic flux leaks between the pole shoes and cores, rather than across the air gap. The ratio of the maximum flux, which exists in the field cores, to the useful flux (*i.e.*, the flux that crosses the air gap) is the **coefficient of leakage.** This coefficient must always be greater than unity and in carefully designed dynamos may be as low as 1.15. It is frequently as high as 1.30. Although the geometry of the leakage-flux paths is not simple, the leakage flux may be determined by approximations with a fair degree of accuracy.

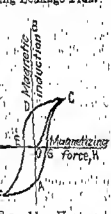

FIG. 11.—Hysteresis Loop.

Magnetic Hysteresis. The magnetization curves shown in Fig. 9 are called **normal curves.** They are taken with the magnetizing force continuously increased from zero. If at any point the magnetizing force be decreased, a greater value of flux density for any given magnetizing force will result. The effect of carrying iron through a complete cycle of magnetization, both positive and negative, is shown in Fig. 11. The resulting curve is called a **hysteresis loop.** It is seen that the flux density lags the magnetizing force. When the positive magnetizing force H returns to zero at O, the induction OD remains. This is called the **remanence.** In order to reduce the induction to zero a negative magnetizing force OE is necessary. OE is the **coercive force.** Permanent magnets operate on the portion DE of the loop, and the area ODE is a criterion of permanent-magnet material. The energy dissipated per cycle is proportional to the area of the loop and is equal to $\frac{1}{4\pi}\int HdB$ ergs per cycle. For moderately high densities the energy loss per cycle varies

With parallel circuits, unity power factor is obtained when the algebraic sum of the quadrature currents is zero. That is, $b_1 + b_2 + b_3 \cdots = 0$.

Three-phase Circuits. Alternating-current generators are usually wound with three armature circuits which are spaced 120 electrical degrees apart on the armature. Hence these coils generate emfs 120 electrical degrees apart. The coils are connected either in Y (star) or in Δ (mesh) as shown in Fig. 24. Whether Y- or Δ-connected, with a balanced load, the three coil emfs E_c and the three coil currents I_c are equal. In the Y connection the line and coil currents are equal, but the line emfs AB, BC, CA are $\sqrt{3}$ times the coil emfs OA, OB, OC, since each is the vector sum of two coil emfs. In the delta connection the line and coil emfs are equal, but I, the line current, is $\sqrt{3}I_c$, the coil current, *i.e.*, it is the vector sum of the currents in the two coils connected to the line. The power of a coil is $E_cI_c \cos \theta$, so that the total power is $3E_cI_c \cos \theta$. If θ is the angle between *coil* current and *coil* voltage, the angle between line current and line voltage will be $(30° \pm \theta)$. In terms of line current and emf, the power is $\sqrt{3}EI \cos \theta$. A fourth or neutral conductor connected to O is sometimes used with the Y connection. The neutral point O is frequently grounded in transmission and distribution circuits. The coil emfs are assumed to be sine waves. Under these conditions they balance, so that in the delta connection the sum of the two coil emfs at each instant is balanced by the third coil emf. Even though the third, ninth, fifteenth . . . . harmonics, $3(2n + 1)f$, where $n = 0$ or an integer, exist in the coil emfs, they cannot appear on the external line of the three-phase Y-connected circuit, except when the neutral conductor is used. In the delta circuit, the same harmonics $3(2n + 1)f$ cause a local current to circulate around the mesh. This may cause a very appreciable heating. In a three-phase system the power

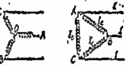

FIG. 24.—Three-phase Connections.

$$P = \sqrt{3}EI \cos \theta \tag{64}$$

the power factor is

$$P/\sqrt{3}EI \tag{65}$$

and the kilovolt-amperes

$$\sqrt{3}EI/1000 \tag{66}$$

Two-phase Circuits. Two-phase generators have two windings spaced 90 electrical degrees apart on the armature. These windings generate emfs differing in time phase by 90 deg. The two windings may be independent and power transmitted to the receiver though the two single-phase circuits are entirely insulated from each other. The two circuits may be combined into a two-phase three-wire circuit such as is shown in Fig. 25, where OA and OB are the generator circuits and $A'O'$ and $B'O'$ are the receiver circuits. The wire OO' is the common wire and under balanced conditions carries a current $\sqrt{2}$ times the current in wires AA' and BB'. For example, if I_c is the coil current, $\sqrt{2}I_c$ will be the value of the current in the common conductor OO'. If E_c be the voltage across OA or OB, $\sqrt{2}E_c$ will be the voltage across AB. The power of a two-phase circuit is twice the power in either coil if the load is balanced. Normally, the voltages OA and OB are equal, and the current is the same in both coils. Owing to non-symmetry and the high degree of

according to the **Steinmetz law**

$$W = \eta B^{1.6} \text{ ergs} \tag{24}$$

Table 9 gives values of η for common magnetic steels.

Table 9. Steinmetz Coefficient

Hard tungsten steel	0.058	Annealed cast steel	0.008
Hard cast steel	0.025	Ordinary sheet iron	0.004
Forged steel	0.020	Pure iron	0.003
Cast iron	0.013	Annealed iron sheet	0.002
Electrolytic iron	0.009	Best annealed sheet	0.001
Soft machine steel	0.009	Silicon steel sheet	0.001

A permanent increase in the hysteresis constant occurs if the temperature of operation remains for some time above 80 C. This phenomenon is known as **aging** and may be much reduced by proper annealing of the iron. Silicon steels containing about 3 percent silicon have a lower hysteresis loss, somewhat larger eddy-current loss, and are practically non-aging.

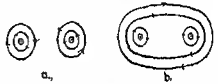

FIG. 12.—*a*. Currents in Opposite Directions. *b*. Currents in Same Direction.

Eddy-current losses, also known as Foucault-current losses, occur in iron subjected to cyclic magnetization. Eddy-current losses are reduced by laminating the iron, which subdivides the emf and increases greatly the length of path of the parasitic currents. Eddy currents have also a screening effect, which tends to prevent the flux penetrating the iron. Hence laminating also allows the full cross section of the iron to be utilized unless the frequency is too high.

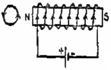

FIG. 13.—Directions of Current and Poles in Solenoid.

Relation of Direction of Magnetic Flux to Current Flow. The direction of the magnetizing force of a current is at right angles to its direction of flow. Magnetic lines about a cylindrical conductor carrying current exist in circular planes concentric with and normal to the conductor. This is illustrated in Fig 12*a*. The ⊕ sign, corresponding to the feathered end of an arrow, indicates current flowing away from the observer; a ⊙ sign, corresponding to the tip of an arrow, indicates current flowing toward the observer.

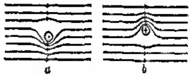

FIG. 14.—Effect of Current on Uniform Magnetic Field.

Corkscrew Rule. The direction of the current and that of the resulting magnetic field are related to each other as the forward travel of a corkscrew and the direction in which it is rotated. **Hand Rule.** Grasp the conductor in the right hand with the thumb pointing in the direction of the current. The fingers will then point in the direction of the lines of flux.

The applications of these rules are illustrated in Figs. 12*a* and 12*b*. If the currents in parallel conductors flow in opposite directions (Fig. 12*a*), the conductors tend to move apart; if the currents in parallel conductors flow in the same directions (Fig. 12*b*), the conductors tend to come together. The magnetic lines act like stretched rubber bands and, in attempting to contract, tend to pull the two conductors together.

unbalancing of this system even under balanced loads, it is not used at the present time for transmission and is little used for distribution.

Quarter-phase Circuit. A quarter-phase circuit is shown in Fig. 26. The windings AC and BD may be independent or connected at O. The voltages AC and BD are 90 deg apart as in two-phase circuits. If a neutral wire OO' be added, three different voltages may be obtained: Let E_1 = voltage $OA = OB = OC = OD$. Voltages AB, BC, CD, $DA = \sqrt{2}E_1$. Voltage $AC = BD = 2E_1$. Because of this multiplicity of voltages and the fact that polyphase power apparatus and lamps may be connected at the same time, this system is still used to some extent in distribution.

FIG. 25.—Two-phase Three-wire Circuit.

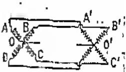

FIG. 26.—Quarter-phase Circuit.

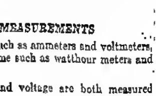
Advantages of Polyphase Power. The advantages of polyphase power over single-phase power are as follows: The output of alternators and most other rotating machinery is from 60 to 90 percent greater when operated polyphase than when operated single phase; pulsating fluxes and corresponding iron losses which occur in many common types of machinery when operated single phase are negligible when operated polyphase; with balanced polyphase loads polyphase power is constant whereas with single phase the power fluctuates over wide limits during the cycle. Because of its minimum number of wires and the fact that it is not easily unbalanced, the three-phase system has for the most part superseded the other polyphase system. (See p. 1739. for polyphase connections of transformers.)

ELECTRICAL INSTRUMENTS AND MEASUREMENTS

Electrical measuring devices that merely indicate, such as ammeters and voltmeters, are called **instruments**; devices that totalize with time such as watthour meters and ampere-hour meters are called **meters**.

Direct-current Instruments. Direct current and voltage are both measured with an indicating instrument based on the principle of the D'Arsonval galvanometer. A coil with steel pivots and turning in jewel bearings is mounted in a magnetic field produced by permanent magnets. The motion is restrained by two small flat coiled springs which also serve to conduct the current to the coil. *The deflections of the coil are read with a* light aluminum pointer attached to the coil and moving over a graduated scale. The same instrument may be used either for current or voltage, but the method of connecting in circuit is different in the two cases. Usually, however, the coil of an instrument to be used as an ammeter is wound with fewer turns of coarser wire than an instrument to be used as a voltmeter and so has lower resistance. The instrument itself is frequently called a **millivoltmeter**. It cannot be used alone to measure voltage of any magnitude since its resistance is so low that it would be burned out if connected across the line. Hence a resistance r' in series with the coil is necessary as indicated in Fig. 27(a) in which r_c is the resistance of the coil. From 0.2 to 750 volts this resistance is usually within the instrument. For higher voltages an external resistance R called an extension coil or multiplier [Fig. 27(b)] is necessary. Let e be the reading of the instrument in volts [Fig. 27(b)], r the resistance of the instrument, R the resistance of the multiplier. Then the total voltage is



(a) Internal resistance (b) With multiplier

FIG. 27.—Voltmeter.

FIG. 28.—Millivoltmeter with Shunt.

The relation of the direction of current in a solenoid helix to the direction of flux is shown in Fig. 13. Figure 14 shows the effect on a uniform field of placing a conductor carrying current in that field and normal to it. In *a* the current flows toward the observer. By applying the corkscrew rule it is seen that the current weakens the field immediately above it and strengthens the field immediately below it. The reverse is true in *b* where the current flows away from the observer.

Figure 14 is illustrative of the force developed on a conductor carrying current in a magnetic field. In *a* the conductor will tend to move upward owing to the stretching of the magnetic lines beneath it. Similarly, the conductor in *b* will tend to move downward. This principle is the basis of motor action (p. 1724).

(For magnets and solenoids see p. 1767.)

DIELECTRIC CIRCUIT

Dynamic and Static Electricity. Electricity in motion such as an electric current is dynamic electricity; electricity at rest is static electricity. The two are identical physically. Since static electricity is frequently produced at high voltage and small quantity, the two are frequently considered as being two different types of electricity.

Capacitors or Condensers

Capacitors (formerly condensers). Two conducting bodies separated by insulation constitute a capacitor. If a positive charge is placed on one plate of a capacitor, an equal negative charge is induced on the other. The medium between the capacitor plates is called a **dielectric**. The dielectric properties of a medium relate to its ability to conduct *dielectric lines*. This is in distinction to its **insulating** properties which relate to its property to conduct *electric current*. For example, air is an excellent insulator but ruptures dielectrically at low voltage. It is not a good dielectric so far as breakdown strength is concerned.

With capacitors

$$Q = CE \quad (25); \qquad C = Q/E \quad (26); \qquad E = Q/C \quad (27)$$

where Q is the quantity in coulombs, C the capacitance in farads, and E the voltage. The unit of capacitance in the practical system is the *farad*. The farad is too large a unit for practical purposes, so that the *microfarad* is used. However, in voltage, current, and energy relations the capacitance must be expressed in farads.

The energy stored in a capacitor

$$W = \tfrac{1}{2}QE = \tfrac{1}{2}CE^2 = \tfrac{1}{2}Q^2/C \text{ joules} \qquad (28)$$

Capacitance of Capacitors. The capacitance of a parallel-plate capacitor (Fig. 15) is

$$C = \kappa A/(4\pi d \times 9 \times 10^5) \text{ microfarads} \qquad (29)$$

where κ is the dielectric constant, A is the area of one plate, sq cm; and d the distance between plates, cm.

The capacitance of **concentric cylindrical** capacitors (Fig. 16) is

$$C = 0.2171\kappa l/[9 \times 10^5 \log_{10} (R_2/R_1)] \text{ microfarads} \qquad (30)$$

where κ is the dielectric constant and l the length, cm. Also

$$C = 0.03882\kappa/\log_{10} (R_2/R_1) \text{ microfarads per mile} \qquad (31)$$

Equation (31) is useful in that it is applicable to cables.

$$E = e(R + r)/r \qquad (67)$$

It is obvious that by using suitable values of R a voltmeter may be made to have several scales.

Instruments themselves can only carry currents of the magnitudes of 0.01 to 0.06 amp. To measure larger values of current the instrument is provided with a shunt R (Fig. 28). The current divides inversely as the resistances r and R of the instrument and the shunt. A low resistance r' within the instrument is connected in series with the coil. This permits some adjustment of the deflection so that the instrument can be adapted to its shunt. In most cases most of the current flows through the shunt, and the current in the instrument is negligible in comparison. Up to 50 and 75 amp the shunt may be incorporated within the instrument. For larger currents it is usually necessary to have the shunt externa. to the instrument and connect the instrument to the potential terminals of the shunt by means of leads. Any given instrument may have any number of ranges by providing it with a sufficient number of shunts. The range of the usual instrument of this type is approximately 50 millivolts. Although the same instrument may be used for voltmeter or ammeter, the moving coils of voltmeters are usually wound with more turns of finer wire. They take approximately 0.01 amp so that their resistance is approximately 100 ohms per volt. Instruments used as ammeters alone operate with 0.04 to 0.06 amp.

Permanent-magnet moving-coil instruments may be used to measure unidirectional pulsating currents or voltages and in such cases will indicate the average value of the periodically varying current or voltage.

Alternating-current Instruments. Instruments for alternating currents may be divided into four types: electrodynamometer, electromagnetic, hot-wire, and electrostatic. Instruments of the **electrodynamometer** type (the most precise) operate on the principle of one coil carrying current, turning in the magnetic field produced by a second coil carrying current taken from the same circuit. If these circuits or coils are connected in series, the torque exerted on the moving system for a given relative position of the coil system is proportional to the square of the current strength and is not dependent on the direction of the current. Consequently, the instrument will have a compressed scale at the lower end and will usually have only the upper two-thirds of the scale range useful for accurate measurement. Instruments of this type ordinarily require 0.04 to 0.08 amp or more in the moving-coil circuit for full-scale deflection. They read the effective or root-mean-square value of the alternating or pulsating current. The wattmeter operates on the electrodynamometer principle. The fixed coil, however, is energized by the current of the circuit, and the moving coil is connected across the potential in series with high resistance. Unless shielded magnetically the foregoing instruments will not, in general, indicate as accurately on direct current as on alternating current because of the effects of external stray magnetic fields. Also reversed readings should be taken. **Electromagnetic** or **soft-iron** instruments consist of a fixed coil which actuates magnetically a light movable iron vane or core; they are rugged, inexpensive, and may be had in ranges of 30 to 750 volts and 0.05 to 100 amp. They measure effective values and have compressed scales as in the case of electrodynamometer instruments. Instruments of the **hot-wire** type depend on the expansion of a wire which is heated by the current or part of the current to be measured. They are used principally in radio work where it is necessary to measure currents of high frequencies. Electrostatic instruments which depend for indication on the attraction of oppositely charged bodies are used occasionally and for high-voltage measurements but have only a very limited field of application, being relatively more expensive and less accurate than the preceding types. The foregoing instruments may all be used with direct current but are less accurate than the permanent-magnet type of instrument.

Alternating-current instruments of the **induction** type (Westinghouse Co.) must be used on a-c circuits of the frequency for which they have been designed. They are rugged and relatively inexpensive and are used principally for switchboards where a long-scale range and a strong deflecting torque are of particular advantage.

Power Measurement in Single-phase Circuits. Wattmeters are not rated primarily in watts, but in amperes and volts. For example, with low power factor the current and voltage coils may be overloaded and yet the needle be well on the scale. The current coil may be carrying several times its rated current, and yet the instrument read zero because the potential circuit is not closed, etc. Hence it is desirable to

The capacitance of two **parallel cylindrical conductors** D cm between centers and having radii of r cm is

$$C = 0.01941/\log_{10}(D/r) \text{ microfarads per mile} \quad (32)$$

In practice, the capacitance to neutral or to an infinite conducting plane midway between the conductors and perpendicular to their plane is usually

FIG. 15.—Parallel-plate Capacitor.

use both an ammeter and a voltmeter in conjunction with a wattmeter when measuring power [Fig. 29(a)]. The instruments themselves consume appreciable power, and correction is oftentimes necessary unless these losses are negligible compared with the power being measured. For example, in Fig. 29(a), the wattmeter reads the I^2R loss in its own current coil (1 to 2 watts) and in the ammeter, as well as the loss in the voltmeter ($=E^2/R$ where R is the resistance of the voltmeter). The losses in the ammeter and voltmeter may be eliminated by short-circuiting the ammeter and disconnecting the voltmeter when reading the wattmeter. If the wattmeter is connected as shown in Fig. 29(b), it measures the power taken by its own potential coil (E^2/R_p) which at 110 volts is 5 to 7 watts. (R_p is the resistance of the potential circuit.) Frequently correction must be made for this power.

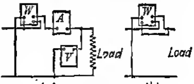

FIG. 29.—Connection of Instruments to Single-phase Load.

Power Measurement in Polyphase Circuits. Three-wattmeter Method. Let ao, bo, and co be any Y-connected three-phase load (Fig. 30). Three wattmeters with their current coils in each line and their potential circuits connected to neutral measure the total power, since the power in each load is measured by one of the wattmeters. The connection oo' may, however, be broken, and the total power is still the sum of the three readings. That is, the power $P = W_1 + W_2 + W_3$. This method is applicable to any system of n wires. The current coil of one wattmeter is connected in each of the n wires. The potential circuit of each wattmeter is connected between its own phase wire and a junction in common with all the other potential circuits. The wattmeters must be connected symmetrically, and the readings of any which read negative must be given the negative sign.

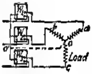

FIG. 30.—Three-wattmeter Method.

In the general case any system of n wires requires at least $n - 1$ wattmeters to measure the power correctly. The $n - 1$ wattmeters are connected in series with $n - 1$ wires. The potential circuit of each is connected between its own phase wire and the wire in which no wattmeter is connected. The application of this method to any four-wire system is shown in Fig. 31.

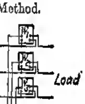

FIG. 31.—Power Measurement in n-wire System.

Three-phase Systems. The three-wattmeter method (Fig. 30) is applicable to any three-phase system. It is commonly used with the three-phase four-wire system. If the loads are balanced, $W_1 = W_2 = W_3$ and the power $P = 3W_1$. Hence W_2 and W_3 may be omitted if their potential circuits are replaced by two resistances enclosed in a Y-box. Each resistance in the Y box must be equal to the resistance of the wattmeter potential circuit.

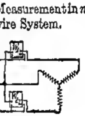

FIG. 32.—Two-wattmeter Method.

The **two-wattmeter** method is most commonly used with three-phase three-wire systems. The method of connecting the wattmeters is shown in Fig. 32. The current coils may be connected in *any* two wires, the potential circuits being connected to the third. It will be recognized that this is adapting the method of Fig. 31 to three wires. With balanced loads the readings of the wattmeters are $W_1 = EI \cos (30° + \theta)$, $W_2 = EI \cos (30° - \theta)$, and $P = W_2 \pm W_1$. θ is the angle of phase difference between coil voltage and current. Since

$$W_1/W_2 = \cos (30° + \theta)/\cos (30° - \theta) \tag{68}$$

the power factor is a function of W_1/W_2. Table 11 gives values of power factor for different ratios of W_1/W_2.

$P = W_2 + W_1$ when $\theta < 60°$.

When $\theta = 60°$, p.f. $= \cos 60° = 0.5$, $W_1 = \cos (30° + 60°) = 0$, $P = W_2$. When $\theta > 60°$, p.f. < 0.5, $P = W_2 - W_1$.

Also $$\tan \theta = \sqrt{3}(W_2 - W_1)/(W_2 + W_1) \tag{69}$$

point rigidly connected with the rolling circle (not necessarily on the circumference) will be an ellipse. If $a = \frac{1}{4}c$, the curve generated will be the four-cusped hypocycloid, or **astroid,** (Fig. 71), whose equation is $x^{2/3} + y^{2/3} = c^{2/3}$. If $a = c$, the epicycloid is the **cardioid,** whose equation in polar coordinates (axes as in Fig. 72) is $r = 2c(1 + \cos\theta)$. Length of cardioid $= 16c$.

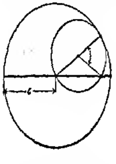

FIG. 70.

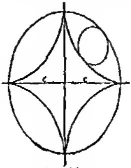
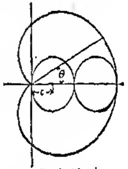


Astroid.
FIG. 71.



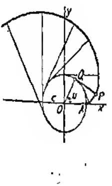
Cardioid.
FIG. 72.

The Epitrochoid (or Hypotrochoid) is a curve traced by any point rigidly attached to a circle of radius a, at distance b from the center, when this circle rolls without slipping on the outside (or inside) of a fixed circle of radius c.

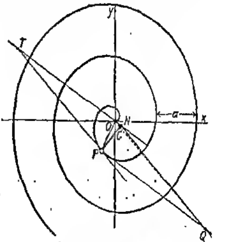
The equations are $x = (c \pm a)\cos\left(\frac{a}{c}u\right) \mp b\cos\left[\left(1 \pm \frac{a}{c}\right)u\right]$,

$y = (c \pm a)\sin\left(\frac{a}{c}u\right) - b\sin\left[\left(1 \pm \frac{a}{c}\right)u\right]$, where $u =$ the angle which the moving radius makes with the line of centers; take the upper sign for the epi- and the lower for the hypo-trochoid. The curve is called prolate or curtate according as $b < a$ or $b > a$. When $b = a$, the special case of the epi- or hypocycloid arises.

The Involute of a Circle is the curve traced by the end of a taut string which is unwound from the circumference of a fixed circle, of radius c. If QP



Involute of Circle.
FIG. 73.



Spiral of Archimedes.
FIG. 74.

is the free portion of the string at any instant (Fig. 73), QP will be tangent to the circle at Q, and the length of QP = length of arc QA; hence the construc-

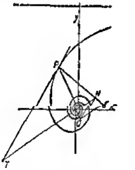
tion of the curve. The equations of the curve in parametric form (axes as in figure) are $x = c(\cos\ u + \text{rad}\ u \sin u)$, $y = c(\sin\ u - \text{rad}\ u \cos u)$, where rad u is the radian measure of the angle u which OQ makes with the x-axis. Length of arc $AP = \frac{1}{2}c(\text{rad}\ u)^2$; radius of curvature at P is QP. Polar equations, in terms of parameter v(= angle POQ), are $r = c \sec v$, rad $\theta = \tan v - \text{rad}\ v$. Here, $r = OP$, and rad θ = radian measure of angle AOP (Fig. 73).

The Spiral of Archimedes (Fig. 74) is traced by a point P which, starting from O, moves with uniform velocity along a ray OP, while the ray itself revolves with uniform angular velocity about O. Polar equation: $r = k\,\text{rad}\ \theta$, or $r = a\ (\theta/360°)$. Here $a = 2\pi k$ = the distance, measured along a radius, from each coil to the next.

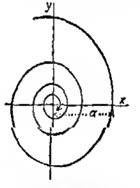
In order to construct the curve, draw radii $O1, O2, O3, \ldots$ making angles $\frac{1}{n}(360°)$, $\frac{2}{n}(360°)$, $\frac{3}{n}(360°)$, . . . with Ox, and along these radii lay off distances equal to $\frac{1}{n}a$, $\frac{2}{n}a$, $\frac{3}{n}a$, . . .; the points thus reached will lie on the spiral. The figure shows one-half of the curve, corresponding to positive values of θ.

Construction for tangent and normal: Let PT and PN be the tangent and normal at any point P, the line TON being perpendicular to OP. Then $OT = r^2/k$, and $ON = k$, where $k = a/(2\pi)$. Hence the construction.

The radius of curvature at P is $R = (k^2 + r^2)^{3/2}/(2k^2 + r^2)$. To construct the center of curvature, C, draw NQ perpendicular to PN and PQ perpendicular to OP; then OQ will meet PN in C. Length of arc $OP = \frac{1}{2}k\,[\text{rad}\ \theta\sqrt{1 + (\text{rad}\ \theta)^2} + \sinh^{-1}(\text{rad}\ \theta)]$. After many windings, arc $OP = \frac{1}{2}r^2/k$, *approximately*.



Hyperbolic Spiral.
FIG. 75.



Logarithmic Spiral.
FIG. 76.

The Hyperbolic Spiral is the curve whose polar equation is $r = a/\text{rad}\ \theta$. To construct the curve, take a series of points along Ox (Fig. 75); through each of these points, with center at O, draw an arc extending into the upper half of the plane; and along each of these arcs lay off a length $= a$. The points thus reached will lie on the curve. A line parallel to the x-axis, at distance a, is an asymptote of the curve. The curve winds around and around the point O without ever reaching it (asymptotic point). The figure shows one-half of the curve, corresponding to positive values of θ. If PT and PN are the tangent and normal at any point P, the line TON being perpendicular to OP,

In a **polyphase wattmeter** the two single-phase wattmeter elements are combined to act on a single spindle. Hence the adding and subtracting of the individual readings are done *automatically*. *The total power* is indicated on one scale. This type of instrument is almost always used on switchboards. The connections of a portable type are shown in Fig. 33.

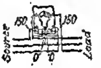

FIG. 33.—Connection for Polyphase Wattmeter in Three-phase Circuit.

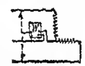

FIG. 34.—Measurement of Two-phase, Three-wire Power with Single Wattmeter.

In the foregoing instrument connections, Y-connected loads are shown. These methods are equally applicable to delta-connected loads. The two-wattmeter method (Fig. 32) is obviously adapted to the two-phase three-wire system (*Figs.* 25 *and* 34). The power in this system may also be measured with one wattmeter. Its current coil is connected in the common wire (Fig. 34), and the potential circuit is connected *first* to one outer wire and then to the other. The power is the sum of the two readings.

Measurement of Energy

Watthour meters record the energy taken by a circuit over some interval of time. Correct registration occurs if the angular velocity of the rotating element at every instant is proportional to the power. The method of accomplishing this with d-c meters is illustrated in Fig. 35. The meter is in reality a small motor. The field coils FF are in series with the line. The armature A is connected across the line, usually in series with a resistance R. The movable field coil F' is in series with the armature A and serves to compensate for friction. C is a small commutator, either of copper or of silver, and the two small brushes are usually of silver. An aluminum disk, rotating between the poles of permanent magnets M, acts as a magnetic brake the torque of which is proportional to the angular velocity of the disk. A small worm and the gears G actuate the recording dials.

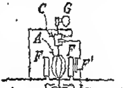

FIG. 35.—Direct-current Watthour Meter.

The following relation, or an equivalent, holds with most types of meter. With each revolution of the disk, K whr are recorded, where K is the **meter constant** found usually on the disk. It follows that the average watts W over any period of time t sec is

$$W = 3{,}600KN/t \qquad (70)$$

where N is the revolutions of the disk during that period. Hence, the meter may be calibrated by connecting standardized instruments to measure the average power taken by the load and by counting the revolutions N for t sec. Near full load, if the meter registers fast, the magnets M should be moved outward radially; if it registers slow, the magnets should be moved inwards. If the meter registers fast at light (5 to 10 percent) load, the starting coil F' should be moved further away from the armature; if it registers slow, F' should be moved nearer the armature. A meter should not register more than 1.5 percent fast or slow, and with calibrated standards it can be made to register to within 1 percent of correct.

in current will produce a much greater proportionate increase in torque (see Fig. 52). This makes the motor particularly well adapted to traction work, cranes, hoists, elevator service, and other types of work which require large starting torques. A study of Eq. (80) shows that with increase in current the numerator changes only slightly, whereas the change in the denominator is nearly proportional to the change in current. Hence the speed of the series motor is practically inversely proportional to the current. With overloads the speed drops to very low values (see Fig. 51). With decrease in load the speed approaches infinity, theoretically. Hence the series motor should always be connected to its load so that it cannot reach unsafe speeds (see Speed Control of Motors, p. 1728).

Differential Compound Motors. The cumulative compound winding of a generator becomes a differential compound winding when the machine is used as a motor. The differential motor, however, is not ordinarily used except occasionally to drive certain textile machines. Its speed may be made more nearly constant than that of a shunt motor, or, if desired, it may be adjusted to increase with increasing load.

Since the speed of the shunt motor is sufficiently constant for most purposes and the differential motor tends toward instability, particularly in starting and on overloads, the differential motor is little used.

Cumulative compound motors develop a more rapid increase in torque with load than shunt motors (Fig. 52); on the other hand, they have much poorer speed regulation (Fig. 51). Hence they are used where larger starting torque than that developed by the shunt motor is necessary, as for example with elevators. They are particularly useful where large and intermittent increases of torque occur as in drives for shears, punches, rolling mills, etc. In addition to the sudden increase in torque which the motor develops with sudden applications of load, the fact that it slows down rapidly and hence causes the rotating parts to give up some of their kinetic energy is another important advantage in that it reduces the peaks on the power plant.

Commutation. The brushes on the commutator of either a motor or generator should be set in such a position that the induced emf in the armature coils undergoing commutation, and hence short-circuited by the brushes, is zero. In practice, this condition can at best be only approximately realized. Frequently conditions are such that it is far from being realized. At no load, the brushes should be set in a position corresponding to the

The induction watthour meter is used with alternating current. Although the d-c meter registers correctly with alternating current, it is more expensive than the induction type, the commutator and brushes may cause trouble, and at low power factors compensation is necessary. In the induction watthour meter the driving torque is developed in the aluminum disk by the joint action of the alternating magnetic flux produced by the potential circuit and by the load current. The driving torque and the retarding torque are both developed in the same aluminum disk, hence no commutator and brushes are necessary. The rotating element is very light, and hence the friction torque is small. Equation (70) applies to this type of meter. When calibrating, the average power W for t sec is determined with a calibrated wattmeter. The friction compensation is made at light loads by changing the position of a small hollow stamping with respect to the potential lug. The meter should also be adjusted at low power factor (0.5 is customary). If the meter is slow with lagging current, resistance should be cut out of the compensating circuit; if slow with leading current, resistance should be inserted.

Power-factor Measurement. The usual method of determining power factor is by the use of voltmeter, ammeter, and wattmeter. The wattmeter gives the watts of the circuit, and the product of the voltmeter reading and the ammeter reading gives the volt-amperes. The power factor is the ratio of the two [see Eqs. (55) and (65)]. Also single-phase and three-phase power-factor indicators, which can be connected directly in circuit, are on the market.

Instrument Transformers

With voltages higher than 600 volts, and even at 600 volts, it becomes dangerous and inaccurate to connect instruments and meters directly into power lines. It is also

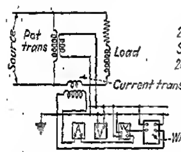

FIG. 36.—Single-phase Connections of Instruments with Transformers.

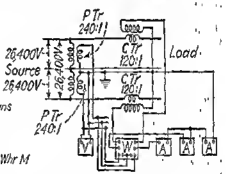

FIG. 37.—Three-phase Connections of Instruments and Instrument Transformers.

difficult to make potential instruments for voltages in excess of 600 volts and ammeters in excess of 100 amp rating. To insulate such instruments from high voltage and at the same time to permit the use of low-range instruments, instrument transformers are used. **Potential transformers** are identical to power transformers except that their volt-ampere rating is low, being 40 to 500 watts. Their primaries are wound for line voltage and their secondaries for 110 volts. **Current transformers** are designed to go in series with the line, and the rated secondary current is 5 amp. The secondary of a current transformer should always be closed when current is flowing; it should never be allowed to become open circuited under these conditions. When open circuited the voltage across the secondary becomes so high as to be dangerous and the flux becomes so large in magnitude that the transformer overheats. The secondaries of both potential and current transformers should be well grounded at one point (Figs. 36 and 37). Instrument transformers introduce slight errors because of small variations in their ratio with load. Also there is slight phase displacement in both current and potential transformers. The readings of the instruments must be multiplied by the instrument transformer ratios. The scales of switchboard instruments are usually calibrated to take these ratios into account.

geometrical neutral of the machine, for under these conditions the induced emf in the coils short-circuited by the brushes is zero. As load is applied, two factors cause sparking under the brushes. The mmf of the armature, or armature reaction, distorts the flux; when the current in the coils undergoing commutation reverses, an emf of self-induction Ldi/dt tends to prolong the current flow which produces sparking. In a generator, armature reaction distorts the flux in the direction of rotation and the brushes should be advanced. In order to neutralize the emf of self-induction the brushes should be set a little ahead of the neutral plane so that the emf induced in the short-circuited coils by the cutting of the flux at the fringe of the next pole is opposite to this emf of self-induction. In a motor the brushes are correspondingly moved backward in the direction opposite rotation.

Theoretically, the brushes should be shifted with every change in load. This is impracticable except occasionally with large machines under constant supervision. Hence the brushes are set in some position intermediate between the no-load and full-load positions. With reversible motors, such as railway motors, the brushes must remain in the no-load neutral. Although the emfs induced in the coils undergoing commutation are relatively small, the resistance of the coils themselves is low so that unless further resistance is introduced the short-circuit currents would be large. Hence, with the exception of certain low-voltage generators, carbon brushes that have relatively high resistance are used almost universally.

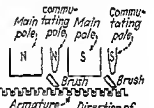

FIG. 53.—Commutating Poles in Motor.

If **commutating poles** are used, the brushes may be allowed to remain in the no-load neutral and at the same time commutation is improved greatly over the entire range of load. **Commutating poles** (or **interpoles**) are small poles between the main poles (Fig. 53) and are excited by a winding in series with the armature. Their function is to neutralize the flux distortion in the neutral plane caused by armature reaction and also to supply a flux that will cause an emf to be induced in the conductors undergoing commutation, opposite and equal to the emf of self-induction. Since armature reaction and the emf of self-induction are both proportional to the armature current, saturation being neglected, they are neutralized theoretically at every load. Commutating poles have made possible d-c generators and motors of very much higher voltage and larger kw ratings than would otherwise be possible.

Commutation difficulties are frequently encountered even in commutating-pole machines. The commutating poles may be connected incorrectly. In a motor, passing from a N main pole in the direction of rotation of the armature, a N commutating pole should be encountered as shown in Fig 53. In a generator under these conditions a S commutating pole should be encountered. The test may be easily made with a compass. If poor commutation is caused by too strong interpoles, the winding may be shunted. If the poles are too weak and the shunting cannot be reduced, they may be strengthened by inserting sheet-iron shims between the pole and the yoke.

Speed Control of Motors

Shunt Motors. In Eq. (79) the speed of a shunt motor $N = K_sE/\phi$ where K_s is a constant involving the design of the motor such as conductors on armature surface and number of poles. Obviously, in order to change

Figure 36 shows the use of instrument transformers to measure the voltage, current, power, and kwhr of a single-phase load. Figure 37 shows the connections that would be used to measure the voltage, current, and power of a 26,400-volt, 600-amp three-phase load.

High-voltage Testing. The most convenient method of measuring high voltage is to measure the voltage induced in a voltmeter coil of few turns interwoven in the high-voltage winding of the step-up transformer but insulated from it. For moderately high voltages (up to 200 kv) the ratio of the voltmeter-coil voltage to the total voltage is in proportion to the number of turns on the two windings. At higher voltages, however, capacitance effects between turns give large errors when this method is used. Sphere gaps may be used for these higher voltages. Calibration data for sphere gaps are given in the A.I.E.E. Standardization Rules. To prevent injuries due to overvoltage it is frequently deemed advisable to connect a sphere gap in parallel with the specimen being tested. The gap is set to a slightly higher voltage than that at which it is desired to test the specimen. Potential transformers are also used to measure high voltages, but they are very expensive for the higher voltages.

Measurement of Resistance

Voltmeter-ammeter Method. A common method of measuring resistance, known as the voltmeter-ammeter or fall-in-potential method, makes use of an ammeter and a voltmeter. In Fig. 38, the resistance to be measured is R. A current I flows through the resistance and ammeter in series, and the drop in potential across the resistance is measured by the voltmeter E. The current shunted by the voltmeter is so small that it may generally be neglected. A correction may be applied if necessary, for the resistance of the voltmeter is generally given with the instrument. The potential difference divided by the current gives the resistance included between the voltmeter leads. As a check, determinations are generally made with several values of current, which may be varied by means of the controlling resistance r. If the resistance to be measured is the armature of a d-c machine and the voltmeter leads are placed upon the brush holders, the resistance determined will include that of the brush contacts. To measure the resistance of the armature alone, the voltmeter leads should be placed directly on the commutator segments upon which the brushes rest but not under the brushes.

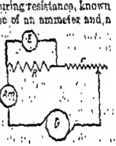

FIG. 38.—Voltmeter-ammeter Method of Resistance Measurement.

Insulation Resistance. Insulation resistance is so high that it is usually given in megohms (10^6 ohms) rather than in ohms. Insulation resistance tests are important, for, although they may not be conclusive they frequently reveal flaws in insulation, poor insulating material, presence of moisture, etc. Such tests are applied to the insulation of electrical machinery from the windings to the frame, to underground cables, to insulators, capacitors, etc.

For moderately low resistances, 1 to 10 megohms, the voltmeter method given in Fig. 39, which shows insulation measurement of the field winding of a generator, may be used. To measure the current flowing when a voltage E is impressed across the resistance R, a high-reading voltmeter V is connected in series with R. The current that flows under this condition with the switch connecting S and A, is $E/(R+r)$ where r is the resistance of the voltmeter. A high-reading voltmeter is necessary, for its resistance is higher than that of a low-reading instrument. Since the method is in reality a comparison of the unknown insulation resistance with the known resistance of the voltmeter, the latter must be comparable to the former, or the deflection of the instrument will be so small that the results will be inaccurate. To determine the impressed voltage E, the

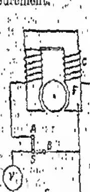

FIG. 39.—Voltmeter Method of Insulation-resistance Measurement.

the speed of a motor, without changing its construction, two factors may be varied, the counter emf E and the flux ϕ.

Armature-resistance Control. The counter emf $E = V - I_aR_a$ where V is the terminal voltage, assumed constant. R_a must be small in order that the armature heating may be maintained within permissible limits. Under these conditions the speed change with load is small. By inserting external resistance, however, into the armature circuit the counter emf E may be made to decrease rapidly with increase in load. That is, $E = V - I_a(R_a + R)$ where R is the external resistance. The resistance R must be inserted in the *armature* circuit only. The advantages of this method are its simplicity, the full torque of the motor is developed at any speed, and the method introduces no commutating difficulties. Its disadvantages are the very poor speed regulation with change of load (Fig 54), the very low efficiency, particularly at the lower speeds and the fact that provision must be made to dissipate the comparatively large power losses in the series resistor. Figure 54 shows typical speed-load curves without and with a series resistance in the armature circuit. The armature efficiency is nearly equal to the ratio of the operating speed to the no-load speed. Hence at 25 percent speed the armature efficiency is practically 25 percent. Frequently the controlling and starting resistances are one and the device is called a **controller**. Starting rheostats themselves are not designed to carry the armature current continuously and must not be used as controllers. The armature resistance method of speed control is frequently used to regulate the speed of ventilating fans where the power demand diminishes rapidly with decrease in speed.

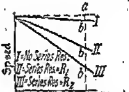

FIG. 54.—Speed-load Characteristics with Armature-resistance Control.

Control by Changing Impressed Voltage. From Eq. (80) it is evident that the speed of a motor may be changed if V is changed by connecting the armature across different voltages. Speed control by this method is accomplished by having mains (usually four), which are maintained at different voltages, available at the motor.

The shunt field of the motor is generally permanently connected to one pair of mains, and the armature circuit is provided with a controller by means of which the operator can readily connect the armature to any pair of mains. Such a system gives a series of distinct and widely separated speeds and generally necessitates the use of field-resistance control, in combination, to obtain intermediate speeds. This method, known as the **multivoltage method**, has the disadvantage that the system is expensive, for it requires several generating machines, a somewhat complicated switchboard, and a number of service wires. The system is used somewhat in machine shops and is extensively used for d-c elevator starting and speed control.

In the **Ward Leonard method**, speed control is obtained by applying variable voltage to the armature. Power for the working motor is obtained from a motor-generator set which runs at constant speed from the supply mains. The field circuit of the generator is excited from the supply mains. The resistance of its field rheostat is sufficient to vary the field current from full value to nearly zero. The armature of the working motor is connected to the armature of the variable-voltage generator. Its field excitation is constant, being connected across the supply mains. Hence any speed from

same voltmeter is used. The switch S connects S and B for this purpose. With these two readings, the unknown resistance is

$$R = r(E - e)/e \tag{71}$$

where e is the deflection of the voltmeter when in series with the resistance to be measured as when S is at A. If a special voltmeter, having a resistance of 100,000 ohms per 150 volts, is available, a resistance of the order of 2 to 3 megohms may be measured very accurately.

When the insulation resistance is too high to be measured with a voltmeter, a sensitive galvanometer may be used. The connections are shown in Fig. 40. The battery should have an emf of at least 100 volts. Radio B batteries are convenient for this purpose. The method involves comparing the unknown resistance with a standard 0.1 megohm. To calibrate the galvanometer the cable is short-circuited (dotted line) and the switch S is thrown to position a. Let the galvanometer deflection be D_1 and the reading of the Ayrton shunt S_1. The short circuit is then removed. The 0.1 megohm is left in circuit since it is usually negligible in comparison with the unknown resistance X. Let the reading of the galvanometer now be D_2 and the reading of the shunt S_2. Then

$$X = 0.1\, S_2D_1/S_1D_2 \tag{72}$$

When the switch S is thrown to position b, the cable is short-circuited and discharges electrostatically.

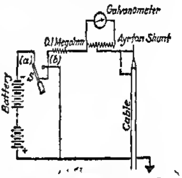

Fig. 40.—Measurement of Insulation Resistance with Galvanometer.

The **Megger** is an instrument that indicates insulation resistance directly on a scale. It consists of a small hand-driven generator which generates approximately 500 volts. A clutch slips when the voltage exceeds the rated value. The current through the unknown resistance flows through a moving element consisting of two coils fastened rigidly together, but which move in different portions of the magnetic field. A pointer attached to the spindle of the moving element indicates the insulation resistance directly. These instruments have a range up to 2,000 megohms, and are very convenient where portability and convenience are desirable.

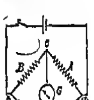

Fig. 41.—Wheatstone Bridge.

The insulation resistance of electrical machinery is of doubtful significance as far as dielectric strength is concerned. It varies widely with temperature, humidity, and cleanliness of the parts. When the insulation resistance falls below the prescribed value, it may, in most cases of good design, be brought to the required standard by cleaning and drying the machine. Hence it may be useful in determining whether or not the insulation is in proper condition for a dielectric test. The A.I.E.E. Standards (5–451) specify minimum value of insulation resistance in megohms = $\dfrac{\text{rated voltage}}{\text{rating in kw} + 1{,}000}$. If the operating voltage is higher than the rated voltage, the operating voltage should be used. The rule specifies that a d-c voltage of 500 be used in testing. If not, the voltage should be specified.

Wheatstone Bridge. Resistances from a fraction of an ohm to 100,000 ohms and more may be measured with a high degree of precision with the Wheatstone bridge (Fig. 41). The bridge consists of four resistances $ABCX$ connected as shown. X is the unknown resistance; A and B are ratio arms, the resistance units of which are in even decimal ohms as 1 – 10 – 100, etc. C is the rheostat arm. A battery or low-voltage source of direct current is connected across ab. A galvanometer G of moderate sensitivity is connected across cd. The values of A and B are so chosen that three or four significant figures in the value of C are obtained. As a first approximation it is well to

zero up to full speed may be obtained by adjusting the generator field current. Because of its cost, complications, and low over-all efficiency, the applications of this system are limited. It has been employed in the operation of large newspaper printing presses and the turning of gun turrets on battleships.

The Ilgner system is based on a principle similar to that of the Ward Leonard system except that the d-c generator is driven with a slip-ring induction motor having external resistance which is automatically controlled with a regulator. The armatures of the generator and work motor are connected electrically, and both are separately excited. Since the set is used principally to supply power to hoists and acts as a balancing set, the motor-generator set is provided with a heavy flywheel. When a heavy load is applied, the regulator inserts resistance in the rotor circuit which slows the motor down and causes the flywheel to give up some of its kinetic energy, thus tending to equalize the loads on the power system.

Control by Changing Field Magnetism. From Eq. (79) it is seen that the speed of a motor is inversely proportional to the magnetic flux ϕ. The flux can be changed either by varying the shunt-field current or by varying the reluctance of the magnetic circuit. The variation of the **shunt-field current** is the simplest and most efficient of all the methods of speed control.

With the ordinary motor, speed variation of 1.5 to 1.0 is obtainable with this method. If attempt is made to obtain greater ratios, severe sparking at the brushes results, owing to the field distortion caused by the armature mmf becoming large in comparison with the weakened field of the motor. Speed ratios as high as 5:1 are, however, obtainable with motors having commutating poles (see p. 1728). Commutating poles not only give the correct mmf for proper commutation but when they are used the brushes may remain in the geometrical neutral. Hence there are no demagnetizing armature ampere-conductors acting on the field to weaken it and thus increase the distortion and speed instability. Since the field current is a small proportion of the total current (1 to 5 percent), the rheostat losses in the field circuit are always small. Hence this method is efficient. Also for any given speed adjustment the speed regulation is excellent, which is another advantage. Because of its simplicity, efficiency, and excellent speed regulation, the control of speed by means of the field current is by far the most common method.

Removable Armature Method. In the Lincoln motor the speed is controlled by changing the position of the armature with respect to the field. For example, if it is desired to increase the speed, the armature is in part moved axially out of the field by means of a hand wheel. This obviously reduces the flux entering the armature. The advantages of this method are that very fine adjustment of speed is obtainable and, at the higher speeds, there is no tendency toward instability such as occurs with field rheostat control. This type of motor is more complicated than the simple motor. It has found extensive application in driving machine tools where fine speed control is essential.

Speed Control of Series Motors. The series motor is fundamentally a variable-speed motor, the speed varying widely from light load to full load and more (see Fig. 51 and p. 1726). From Eq. (80) the speed for any value of ϕ, or current, may be changed by varying the impressed voltage. Hence the speed may be controlled by inserting resistance in series with the motor. This method, which is practically the same as the armature-resistance control

make A and B equal. When the bridge is in balance,

$$X/C = A/B \tag{73}$$

The positions of the battery and galvanometer are interchangeable. There are many modifications of the bridge which adapt it to measurements of very low resistances and also to a-c measurements.

Potentiometer. The principle of the potentiometer is shown in Fig. 42. ab is a slide wire, and bc consists of a number of equal individual resistances between contacts. A battery Ba the emf of which is approximately 2 volts supplies current to this wire through the adjustable rheostat R. A slider m makes contact with ab, and a contactor m' connects with the contacts in bc. A galvanometer G is in series with the wire connecting to m. By means of the double-throw double-pole switch Sw either the standard cell (Weston cell p. 1697) or the unknown emf may be connected to mm' through the galvanometer G. The potentiometer is standardized by throwing Sw to the standard-cell side, setting mm' so that their positions on ab and bc correspond to the emf of the standard cell (see p. 1697). The rheostat R is then adjusted until G reads zero. The unknown emf is measured by throwing Sw to $E.M.F.$ and adjusting m and m' until G reads zero. The advantage of this method of measuring emf is that when the potentiometer is in balance no current is taken from either the standard cell or the source of E.M.F. Potentiometers seldom exceed 1.6 volts in range. To measure voltage in excess of this, a *volt box* which acts as a multiplier is used. To measure current, the voltage drop across a standard resistance of suitable value is measured with the potentiometer. For example, with 50 amp a 0.01-ohm standard resistance gives a voltage drop of 0.5 volt which is well within the range of the potentiometer.

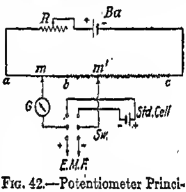

Fig. 42.—Potentiometer Principle.

Potentiometers of low range are used extensively with thermocouple pyrometers. Figure 42 merely illustrates the principle of the potentiometer. There are many modifications, conveniences, etc., not shown in Fig. 42.

Direct-current Generators

All electrical machines are comprised of a magnetic circuit of iron (or steel) and an electric circuit of copper. In a generator the armature conductors are rotated so that they cut the magnetic flux coming from and entering the field poles. In the d-c generator (except the unipolar type) the emf induced in the individual conductors is alternating, but this is rectified by the commutator and brushes, so that a unidirectional current flows to the external circuit.

The induced emf in a generator (or motor)

$$E = \phi ZNP/60P'10^8 \text{ volts} \tag{74}$$

where ϕ is the flux entering the armature from one north pole; Z the total number of conductors on the armature; N the speed, rpm; P the number of poles; and P' the number of parallel paths through the armature. Since with a given generator, Z, P, P' are fixed, the induced emf

$$E = K\phi N \text{ volts} \tag{75}$$

where K is a constant. When current flows from the armature, the terminal volts

$$V = E - I_aR_a \tag{76}$$

where I_a is the armature current and R_a the armature resistance including the brush and contact resistance which vary somewhat.

method for shunt motors, has the same objections of low efficiency and poor regulation with fluctuating loads. It is extensively used, however, in controlling the speed of hoist and crane motors.

The series-parallel system of series-motor speed control is almost universally used in electric traction. At least two motors are necessary. The two motors are first connected in series with each other and with the starting resistance. The starting resistance is gradually cut out, and the motors reach approximately half speed. Both motors take the same current, and each can develop full torque. This condition of operation is efficient since there is no external resistance in circuit. When the controller is moved to the next position, the motors are connected in parallel with each other and each in series with starting resistances. Full speed of the motors is obtained by gradually cutting out these resistances. Connecting the two motors in series on starting reduces the current to one-half the value that would be required for a given torque were both motors connected in parallel on starting. The power taken from the trolley is halved, and an intermediate running speed is efficiently obtained.

In the **multiple-unit** method of speed control which is used for electric railway trains, the starting contactors, reverser, etc., for each car are located under that car. The relays operating these control devices are actuated by energy taken from the train line consisting usually of seven wires. The train line runs the entire length of the train, the connections between the individual cars being made through the couplers. The train line is energized by the action of the motorman operating any one of the small master controllers which are located in each car. Hence corresponding relays, contactors, etc., in every car all operate simultaneously. High accelerations may be reached with this system because of the large tractive effort exerted by the wheels on every car.

Alternating-current Generators

Construction. In the usual alternator the armature or stator is the stationary member. This construction has many advantages. It is possible to make the slots any reasonable depth, since the tooth necks increase in cross section with increase in depth of slot; this is not true of the rotor. The large slot section which is thus obtainable gives ample space for copper and insulation. The conductors from the armature to the bus bars can be insulated throughout their entire lengths, since no rotating or sliding contacts are necessary. The insulation in a stationary member does not deteriorate as rapidly as that on a rotating member, for it is not subjected to centrifugal force or to any considerable vibration.

The **rotating member** is ordinarily the field. There are two general types of field construction, the **salient-pole type** and the **cylindrical or non-salient pole type**. The salient-pole type is used almost entirely for slow and moderate-speed generators since this construction is the least expensive and permits ample space for field copper.

It is not practicable to employ salient poles in high-speed turboalternators because of the excessive windage and the difficulty of obtaining sufficient mechanical strength. The **cylindrical type** consists of a cylindrical steel forging with either parallel or radial slots in which the field copper, usually in strip form, is placed. The fields are ordinarily excited at low voltage, 125 and 250 volts, the current being conducted to the rotating member by means of slip rings and brushes. The field power is ordinarily only 1 or 2 percent the rated power of the machine (see Table 14, p. 1730).

There are three standard types of d-c generators: the **shunt generator**, the **series generator**, and the **compound generator**. The series generator is nearly obsolete.

Shunt Generator. The field of the shunt generator in series with its rheostat is connected directly across the armature as shown in Fig. 43. This machine maintains approximately constant terminal voltage over its working range of load. An external characteristic of the generator is shown in Fig. 44. As load is applied the terminal voltage drops owing to the armature-resistance drop [Eq. (76)] and armature reaction which decreases the flux. The drop in terminal voltage reduces the field current which in turn reduces the flux, hence the induced emf, etc. At some point B, usually well above rated current, the foregoing reactions become cumulative and the machine commences to break down. The current reaches a maximum value and then decreases to nearly zero at short circuit. With large machines, point B is well above rated current, the operating range being between O and A. The voltage may be maintained constant by means of the field rheostat. Automatic regulators which operate through the field rheostat are frequently used to maintain constant voltage (see p. 1735). Shunt generators are commonly used in city substations which are all tied together through the network of feeders and mains. Their stability when in parallel is a distinct advantage for this service. If a generator fails to build up (1) the load may be connected; (2) the field resistance may be too high; (3) the field circuit may be open; (4) the residual magnetism may be insufficient; (5) the field connection may be reversed.

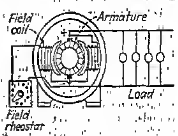

FIG. 43.—Shunt Generator.

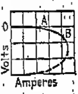

FIG. 44.—Shunt-generator Characteristic.

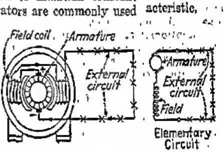

FIG. 45.—Series Generator.

Series Generator. In the series generator (Fig. 45) the entire load current flows through the field winding, which consists of relatively few turns of wire of sufficient size to carry the entire load current without undue heating. The field excitation, and hence the terminal voltage, depends on the magnitude of the load current. An external characteristic showing the relation between load current and terminal voltage is given in Fig. 46. When used as a booster the series generator operates on the left-hand side of the characteristic (Fig. 46); when used as a constant-current generator it operates on the right-hand side of the characteristic. The principal application of series generators was constant-current series arc lighting. They have been replaced almost entirely by constant-current transformers operating in combination with mercury-arc rectifier tubes.

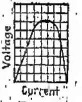

FIG. 46.—External Characteristic of Series Generator.

Compound-wound Generators (Fig. 47). By the addition of a series winding to a shunt generator the terminal voltage may be automatically

Classes of Alternators. Alternators may be divided into three general classes: (1) the slow-speed engine driven type; (2) the moderate speed water-wheel-driven type; and (3) the high-speed turbine-driven type. In (1) a hollow box frame is used as the stator support and the field consists of a spider to which a large number of salient poles are attached, usually bolted. The speed seldom exceeds 75 to 90 rpm, although it may run as high as 150 rpm. Water-wheel alternators also have salient poles which are usually dovetailed to a cylindrical spider consisting of steel plates riveted together. Their speeds range from 80 to 600 rpm and sometimes higher, although the 9,000 kva Keokuk alternators rotate at only 58 rpm, operating at a very low head. The speed rating of direct-connected water-wheel alternatore decreases with decrease in head. It is desirable to operate alternators at the highest permissible speed since the weight and costs diminish with increase in speed. Water-wheel-driven alternators must be able to run at double speed, as a precaution against accident should the governor fail to shut the gate sufficiently rapidly in case of opening of the circuit breakers or should the governing mechanism become inoperative.

Turbine-driven alternators operate at speeds of 720 to 3,600 rpm. Direct-connected exciters, belt-driven exciters from the alternator shaft, and separately driven exciters are used. In large stations separately driven (usually motor) exciters supply the excitation energy to excitation bus bars. Steam-driven exciters and storage batteries are frequently held in reserve. With slow-speed alternators the belt-driven exciter is frequently used because it can be driven at higher speed, thus reducing the cost.

Alternator Design. At the present time single-phase alternators are seldom built. For single-phase service two phases of a standard three-phase Y-connected alternator are used. A single-phase load or unbalanced three-phase load produces flux pulsations in the magnetic circuits of alternators, which in the past have caused serious difficulties. Two-phase windings consist of two similar single-phase windings displaced 90 electrical space degrees on the armature and ordinarily occupying all the slots on the armature. The most common type of winding is the three-phase lap- or wave-wound two-layer barrel-type of winding. In three-phase windings three windings are spaced 120 electrical space degrees apart, the individual phase belts being spaced 60 deg apart. Usually, all the slots on the armature are occupied. Standard voltages are 550, 1,100, 2,200, 6,600, 13,200, and 20,000 volts. It is much more difficult to insulate for 20,000 volts than it is for the lower voltages. However, if the power is to be transmitted at this voltage, its use would be justified by the saving of transformers. In machines of moderate and larger ratings it is common to generate at 6,600 and 13,200 volts if transformers must be used. The higher voltage is preferable, particularly for the higher ratings, because it reduces the cross section of the connecting leads and bus bars.

The **standard frequencies** in the country are 60 and 50 cycles for light and power; 50 cycles is less common than 60 cycles, its principal use being in southern California. Lower frequencies are not desirable for lighting loads because of the objectionable flicker of the lamps. For power purposes only, 25 cycles is frequently used. For example, power for conversion to direct current at railway substations and power for railway electrification is usually 25 cycles; induction motors, synchronous converters, and series commutating motors operate more satisfactorily at that frequency. The frequency of a synchronous machine

$$f = P \times \text{rpm}/120 \qquad (84)$$

maintained very nearly constant, or, by properly proportioning the series turns, the terminal voltage may be made to increase with load to compensate for loss of voltage in the line, so that approximately constant voltage is maintained at the load. If the shunt field is connected outside the series field (Fig. 47), the machine is long shunt; if the shunt field is connected inside the series field, *i.e.*, directly to the armature terminals, it is short shunt. So far as the operating characteristic is concerned, it makes little difference which way a machine is connected.

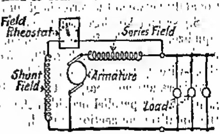

FIG. 47.—Compound-wound D-c Generator.

Compound-wound generators are chiefly used for small isolated plants and for generators supplying a purely motor load subject to rapid fluctuations such as in railway work. When first putting a compound generator in service the shunt field must be so connected that the machine builds up. The series field is then connected so that it aids the shunt field. Sometimes the residual magnetism is reversed by a short circuit feeding back through the series fields in the reversed direction. The generator will not then build up until the residual magnetism is reversed, temporary external excitation usually being necessary. Figure 48 gives the characteristics of a 200-kw 600-volt compound-wound generator.

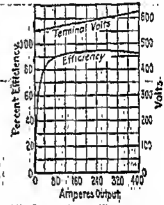

FIG. 48.—Characteristics of a 200-kw Compound-wound D-c Generator.

Parallel Operation of Shunt Generators. It is desirable to operate generators in parallel in order that the station capacity may be adapted to the load. Shunt generators, because of their drooping characteristics (Fig. 44), are inherently stable when in parallel. To connect shunt generators in parallel it is necessary that the switches be so connected that like poles are connected to the same bus bars when the switches are closed. Assume one generator to be in operation; to connect another generator in parallel with it, the incoming generator is first brought up to speed and its terminal voltage adjusted to a value slightly greater than the bus-bar voltage. This generator may then be connected in parallel with the other without difficulty. The proper division of load between them is adjusted by means of the field rheostats and is maintained automatically if the machines have similar voltage-regulation characteristics.

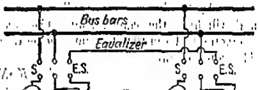

FIG. 49.—Connections for Compound-wound Generators Operating in Parallel.

Parallel Operation of Compound Generators. As a rule, compound generators have either flat or rising voltage characteristics. Therefore, when

where P is the number of poles. Alternators are rated in kilovolt-amperes (kva) rather than in kilowatts, for heating, which determines the rating, is dependent only on the current and is independent of power factor. If the kilowatt rating is specified, the power factor should also be specified.

Induced EMF. The induced emf per phase in an alternator

$$E = 2.22k_b k_p \Phi f Z 10^{-8} \text{ volts per phase} \tag{85}$$

k_b is the breadth factor or belt factor (usually 0.9 to 1.0) and depends on the *number of slots per pole per phase*; k_p *is the pitch factor* $= 1.0$ for full pitch; Φ is the total flux entering the armature from one north pole and is assumed to be sinusoidally distributed along the air gap; f is the frequency; and Z is the number of series conductors per phase.

Regulation. The terminal voltage of an alternator at constant frequency *and field excitation depends not only on the current load but on the power* factor as well. This is illustrated in Fig 55 which shows the voltage-current characteristics of an alternator with lagging current, leading current, and in-phase current (p.f. = 1.00). With leading current the voltage may actually rise with increase in load; the rate of voltage decrease with load becomes greater as the lag of the current increases. The regulation of an alternator is defined by the A.I.E.E. Standard Rules (No. 7) as follows: *In constant-potential alternators, the regulation is the rise in voltage (when the specified load at specified power factor is reduced to zero) expressed in percentage of rated voltage.* For example, in Fig. 55 the regulation under each condition is

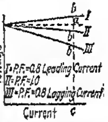

Fig. 55.—Alternator Characteristics.

$$100(ac - bc)/bc \tag{86}$$

With leading current the regulation may be negative.

Three factors affect the regulation of alternators, the **effective armature resistance**, the **armature leakage reactance**, and **armature reaction.** With alternating current the armature loss is greater than the value obtained by multiplying the square of the armature current by the ohmic resistance. This is due to hysteresis and eddy-current losses in the iron adjacent to the conductor and to the alternating flux producing losses in the conductors themselves. Also the current is not distributed uniformly over conductors in the slot, but the current density tends to be greatest in the top of the slot. These factors all have the effect of increasing the resistance. The ratio of effective to ohmic resistance varies from 1.2 to 1.5. The **armature leakage reactance** is due to the flux produced by the armature current linking the conductors in the slots and also the end connections.

The armature mmf reacts on the field to change the value of the flux. With a single-phase alternator and with an unbalanced load on a polyphase alternator this mmf is pulsating and causes iron losses in the field structure. With polyphase machines under a constant balanced load the armature mmf is practically constant in magnitude and fixed in its relation to the field poles. Its direction is determined by the power factor of the load.

A component of current in phase with the no-load induced emf merely distorts the field by strengthening the trailing pole-tip and weakening the leading pole-tip. A component of current lagging the induced emf by 90 deg weakens the field without distortion. A component of current leading the induced emf by 90 deg strengthens the field without distortion. Ordinarily, both cross-magnetization and one of the other components are acting simultaneously.

connected in parallel, they are inherently unstable. Stability may, however, be obtained by using an equalizer connection (Fig. 49) which connects the terminals of the generator at the junctions of the series fields. This connection is of low resistance so that any increase of current divides proportionately between the series fields of the two machines. The equalizer switch (E.S.) should be closed first and opened last, if possible. In practice, the equalizer switch is often one blade of a three-pole switch, the other two being the bus switch S, as in Fig. 49. When compound generators are used on a three-wire system, two series fields—one at each armature terminal—and two equalizers are necessary. It is possible to operate any number of compound generators in parallel provided their characteristics are not too different and the equalizer connection is used.

Table 12. Approximate Test Performance of Compound Wound D-c Generators with Commutating Poles
(Westinghouse Electric & Mfg. Co.)

Kw	Voltage	Amp	Efficiency, percent		
			½ load	¾ load	4/4 load
5	125	40	78.0	81.0	82.0
10	125	80	83.5	87.0	88.0
25	125	200	86.5	88.5	89.5
50	125	400	86.0	89.0	90.0

1,000	250	4,000	92.1	92.6	92.1

(See Table 22, p. 1764, for the approximate full-load currents of motors.)

Direct-current Motors

Motors operate on the principle that a conductor carrying current in a magnetic field tends to move at right angles to that field (see Fig. 14, p. 1980). The ordinary d-c generator will operate entirely satisfactorily as a motor and will have the same rating. The conductors of the motor rotate in a magnetic field and therefore must generate an emf just as does the generator. The induced emf

$$E = K\phi N \tag{77}$$

where K is a constant, ϕ the flux entering the armature from one north pole, and N the speed in rpm [see Eq. (75), p. 1997]. This emf is in opposition to the terminal voltage and tends to oppose current entering the armature. Its value is

$$E = V - I_a R_a \tag{78}$$

where V is the terminal voltage, I_a the armature current, and R_a the armature resistance [compare with Eq. (76)]. From Eq. (77) it is seen that the speed

$$N = K_s E/\phi \tag{79}$$

when $K_s = 1/K$. This is the fundamental speed equation for a motor. By substituting in Eq. (78)

$$N = K_s(V - I_a R_a)/\phi \tag{80}$$

which is the general equation for the speed of a motor.

The foregoing effects are called **armature reaction**. Frequently the effects of armature reactance and armature reaction can be combined into a single quantity.

It is difficult to determine the regulation of an alternator by actual loading, even when in service, owing to the difficulty of obtaining, controlling, and absorbing the large balanced loads. Hence methods of **predetermining regulation without actually loading** the machine are used.

Synchronous-impedance Method. Both armature reactance and armature reaction have the same effect on the terminal voltage. In the synchronous-impedance method the alternator is considered as having no armature reaction, but the armature reactance is increased a sufficient amount to account for the effect of armature reaction. The vector diagram for a current I lagging the terminal voltage V by an angle θ is shown in Fig. 56. The power factor of the load is $\cos \theta$; IR is the effective armature-resistance drop and is parallel to I; IX_s is the synchronous-reactance drop and is at right angles to I and leading it by 90 deg. IX_s includes both the reactance drop and the drop in voltage due to armature reaction.

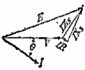

FIG. 56.—Vector Diagram for Synchronous-impedance Method.

That part of IX_s which replaces armature reaction is in reality a fictitious quantity. The synchronous-impedance drop is given by IZ_s. The no-load or open-circuit voltage

$$E = \sqrt{(V \cos \theta + IR)^2 + (V \sin \theta \pm IX_s)^2} \text{ volts} \tag{87}$$

All quantities are per phase. The negative sign is used with leading current.

$$\text{The regulation} = 100(E - V)/V \tag{88}$$

(see p. 1733). With leading current E may be less than V and a negative regulation results.

The synchronous impedance is determined from an open-circuit and a short-circuit test, made with a weak field. The voltage E' on open circuit is divided by the current I' on short circuit for the same value of field current.

$$Z_s = E'/I', \qquad X_s = \sqrt{Z_s^2 - R^2} \text{ ohms} \tag{89}$$

Since the synchronous reactance is determined at low saturation of the iron and used at high saturation, the method gives regulations that are too large; hence it is called the *pessimistic method*.

MMF Method. In the mmf method the alternator is considered as having no armature reactance but the armature reaction is increased by an amount sufficient to include the effect of reactance. That part of armature reaction which replaces the effect of armature reactance is in reality a fictitious quantity. To obtain the data necessary for computing the regulation, the alternator is short-circuited and the field adjusted to give rated current in the armature. The corresponding value of field current I_2 is read. The field is then adjusted to give voltage E' equal to rated terminal voltage $+ IR$ drop ($= V + IR$ vectorially, Fig. 57) on open circuit and the field current I' read.

I_2 is 180 deg from the current vector I, and I' leads E' by 90 deg (Fig. 57). The angle between I' and I_2 is $90 - \theta + \phi$, but since ϕ is small it can usually be neglected. The vector sum of I_2 and I' is I_0. The open-circuit voltage E corresponding to I_0 is the no-load voltage and may be found on the saturation curve. The regulation is then found from Eq. (88). This method gives a value of regulation less than the actual value and hence is called the *optimistic*

The torque developed by an armature is proportional to the flux and to the armature current. That is

$$T = K_1 \phi I_a \tag{81}$$

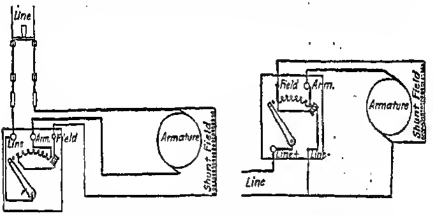
when K_1 is a constant. The torque at the pulley is slightly less than the developed torque by the torque necessary to overcome the rotational losses. Let VI be the motor input. The output is $VI\eta$ where η is the efficiency. The horsepower

$$P_H = VI\eta/746 \tag{82}$$

and the torque

$$T = 33{,}000 P_H/2\pi N. \tag{83}$$

Shunt Motor. In the shunt motor (Fig. 50) the flux is substantially constant and I_aR_a is 2 to 6 percent of V. Hence, from Eq. (80), the speed varies only slightly with load so that the motor is adapted to work requiring constant speed. The speed regulation of constant-speed motors is defined by the A.I.E.E. Standards as follows: In constant-speed d-c motors the regulation



(a) Three-point Box. (b) Four-point Box.

FIG. 50.—Connections for Shunt D-c Motors and Starters.

is the ratio of the difference between rated-load and no-load speeds to the rated-load speed at the final temperature attained at operation under rated load for the time specified in the rating. For example, in Fig. 54 the regulation under each condition is practically $(ac - bc)/bc$ (see Fig. 51). Also from Eq. (81) it is seen that the torque is practically proportional to the armature current (see Fig. 52). The motor is able to develop full-load torque and more on starting, but the ordinary starter is not designed to carry the current necessary for starting under load. The shunt motor is used to drive constant-speed line shafting, for machine tools, etc. Since its speed may be efficiently varied it is very useful when adjustable speeds are necessary, such as individual drive for machine tools (see p. 1751).

Shunt-motor Starters. At standstill the counter emf of the motor is zero and the armature resistance is very low. Hence, except in motors of very small size, series resistance in the armature circuit is necessary on starting. The field must, however, be connected across the line in order that it may obtain full excitation.

Figure 50 shows the two common types of starting boxes used for starting shunt motors. The armature resistance remains in circuit only during starting. In the **three-point box** (Fig. 50(a)) the starting lever is held, against the force of a spring, in the running position, by an electromagnet in

method. The actual regulation lies somewhere between the values obtained by the two methods but is more nearly equal to the value obtained by the mmf method.

Voltage regulators operate to maintain the bus-bar voltage constant and act usually through the field of the exciter. In the Tirrill regulator the field resistance of the exciter is short-circuited temporarily by contacts when the bus-bar voltage drops. Actually, the contacts are vibrating continuously, the time that they are closed depending on the value of the bus-bar voltage. The General Electric Co. manufactures a direct-acting regulator in which the regulating rheostat is part of the regulator itself. The rheostat consists of stacks of graphite plates, each plate being pivoted at the center. Tilting the plates changes the path of the current through the rheostat and thus changes the resistance. The plates are tilted by a sensitive torque armature which is actuated by variations of voltage from the normal value.

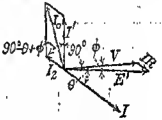


FIG. 57.—Vector Diagram for MMF Method.

Parallel Operation of Alternators. The kilowatt division of load between alternators in parallel is determined entirely by the speed-load characteristics of their prime movers and not by the characteristics of the alternator's themselves. No appreciable adjustment of kilowatt load between alternators in parallel can be made by means of their field rheostats, as with d-c generators. Consider Fig. 58, which gives the speed-load characteristics in terms of frequency of two alternators, No. 1 and No. 2, these characteristics being of course the speed-load characteristics of their prime movers. These speed-load characteristics are drooping, which is necessary for stable parallel operation. The total load on the two machines is $P_1 + P_2$ kw. Both machines must be operating at the same frequency f_1. Hence alternator 1 must be delivering P_1 kw, and alternator 2 must be delivering P_2 kw (the small alternator losses being neglected). If, under the foregoing conditions, the field of either machine is strengthened it cannot deliver a greater kilowatt load, for its prime mover can deliver more power only by dropping its speed. This is impossible, for both alternators must operate always at the same frequency f_1. For any fixed total power load, the division of kilowatt load between alternators can be changed only by modifying in some manner the speed-load characteristics of their prime movers, such, for example, as changing the tension in the governor spring. Alternators in parallel are of themselves in stable equilibrium. If the driving torque of one machine is increased, the resulting electrical reactions between the machines cause a circulating current to flow between machines. This current puts more electrical load on the machine whose driving torque is increased and tends to produce motor action in the other machines. In an extreme case, the driving torque of one prime mover may be removed entirely and its alternator will operate as a synchronous motor, driving the prime mover mechanically.

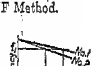

FIG. 58.—Speed-load Characteristics of Alternators in Parallel.

Variations in driving torques cause currents to circulate between alternators, transferring power which tends to keep the alternators in synchronism. If the power transfer takes the form of recurring pulsations, it is called **hunting**. Hunting may be reduced by building heavy copper grids called **amortisseur**

series with the field circuit, so that, if the field circuit is interrupted or the line voltage becomes too low, the lever is released and the armature circuit is opened automatically. In the **four-point starting box** the electromagnet is connected directly across the line, as shown in Fig. 50(*b*). In this type the arm is released instantly upon failure of the line voltage. In the other type some time elapses before the field current drops enough to effect the release. Some starting rheostats are provided with an overload device so that the circuit is automatically interrupted if too large a current is taken by the armature. The four-point box is used where a wide speed range is obtained by means of the field rheostat. The electromagnet is not then affected by changes in field current.

In large motors and in many small motors, automatic starters are frequently used. The advantages of the automatic starter are that the current is held between certain maximum and minimum values so that the circuit does not become opened by too rapid starting as may occur with manual operation; the acceleration is smooth and nearly uniform; relay contactors

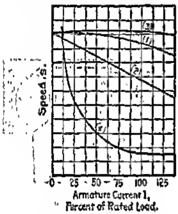

FIG. 51.

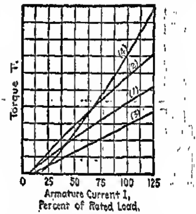

FIG. 52.

Speed and Torque Characteristics of D-c Motors.

(1) Shunt motor; (2) compound motor; (3) differential compound motor; (4) series motor.

of large current capacity are not difficult to design; the resistors and contactors may be placed in any convenient place; the controllers need only be designed to carry the small currents necessary to operate the relays. In modern automatic starters the resistances in series with the armature are successively short-circuited by contactors operated by relays. Any one relay is prevented from operating and cutting out further resistance until the current has dropped to some predetermined value. Since workmen can stop and start a motor merely by the pushing of a button, there results considerable saving by the shutting down of the motor when it is not needed. Automatic starters are very essential to elevator motors in order that smooth rapid acceleration with frequent starting and stopping may be obtained. Also automatic starting is very necessary with multiple-unit operation of electric-railway cars and with rolling-mill motors which are continually subjected to rapid acceleration, stopping, and reversing.

Series Motor. In the series motor the armature and field are in series. Hence, if saturation is neglected, the flux is proportional to the current and the torque [Eq. (81)] varies as the current squared. Therefore any increase

[a] Excitation for these ratings is usually at 250 volts.

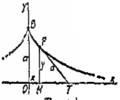
or damper windings into the pole faces. Turbine- and water-wheel-driven alternators are much better adapted to parallel operation than are alternators which are driven by reciprocating engines, because of their uniformity of torque.

Increasing the field current of an alternator in parallel with others causes it to deliver a greater lagging component of current. Since the character of the load determines the total current delivered by the system the lagging components of current delivered by the other alternators must decrease and may even become leading components. Likewise if the field of one alternator is weakened it delivers a greater leading component of current and the other machines deliver components of current which are more lagging. These leading and lagging currents do not affect appreciably the division of kilowatt load between the alternators. They do, however, cause unnecessary heating in the armatures of the alternators. The fields of all alternators should be so adjusted that the heating due to the quadrature components of currents is a *minimum. With two alternators having equal armature resistances this* occurs when both deliver equal quadrature currents.

Armature reactance between machines in parallel is desirable. If not too great it stabilizes their operation by producing the synchronizing action. Alternators with too little reactance are sensitive, and, if connected in parallel with slight phase displacement or inequality of voltage, considerable disturbance results. Armature reactance also reduces the current on short circuit. Frequently, external power-limiting reactances are connected in

then $OT = a$, and $ON = r^2/a$. **Hence a construction for the tangent and normal.** Radius of curvature at P is $R = r/\sin^3 v$, where v = angle between OP and the tangent at P. **Construction:** At N draw a perpendicular to PN, meeting PO in Q; at Q draw a perpendicular to PQ, meeting PN in C; then C is the center of curvature for the point P.

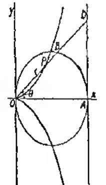
The Logarithmic Spiral (Fig. 76), is a curve which cuts the radii from O at a constant angle v, whose cotangent is m. Polar equation: $r = ae^{m \text{ rad } \theta}$. Here a is the value of r when $\theta = 0$. For large negative values of θ, the curve winds around O as an asymptotic point. If PT and PN are the tangent and normal at P, the line TON being perpendicular to OP (not shown in fig.), then $ON = rm$, and $PN = r\sqrt{1+m^2} = r/\sin v$. Radius of curvature at P is PN. The evolute of the spiral is an equal spiral whose axis makes an angle $\frac{1}{2}\pi - (\log_e m)/m$ with the axis of the given spiral. Area swept out by the radius r from $r = 0$ (where $\theta = -\infty$) to $r = r$, is $A = r^2/(4m)$ = half the triangle OPT. Length of arc from O to $P = s = r/\cos v = PT$.



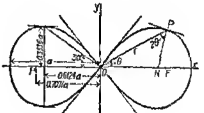
Tractrix.
Fig. 77.

The Tractrix, or Schiele's Anti-friction Curve (Fig. 77), is a curve such that the portion PT of the tangent between the point of contact and the x-axis is constant $= a$. Its equation is $x = \pm a\left[\cosh^{-1}\frac{a}{y} - \sqrt{1 - \left(\frac{y}{a}\right)^2}\right]$, or, in parametric form, $x = \pm a\,[t - \tanh t]$, $y = a/\cosh t$. (For tables of hyperbolic functions, see p. 60.) The x-axis is an asymptote of the curve. Length of arc $BP = a \log_e (a/y)$. The evolute (locus of centers of curvature) is the catenary whose lowest point is at B, and whose directrix is Ox.

The Cissoid (Fig. 78) is the locus of a point P such that OP, laid off on a variable ray from O, is equal to BD, the portion of the ray lying between a fixed circle through O and a fixed tangent at the point A opposite O. If a is the radius of the circle, the polar equation is $r = 2a \sin^2\theta / \cos\theta$. Rectangular equation, $y^2(2a - x) = x^3$.



Cissoid.
Fig. 78.

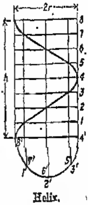


Lemniscate.
Fig. 79.

The Lemniscate (Fig. 79) is the locus of a point P the product of whose distances from two fixed points F, F' is constant, equal to $\frac{1}{2}a^2$. The distance $FF' = a\sqrt{2}$. Polar equation is $r = a\sqrt{\cos 2\theta}$. Angle between OP and the normal at P is 2θ. The two branches of the curve cross at right angles at O.

Maximum y occurs when $\theta = 30°$ and $r = a/\sqrt{2}$, and is equal to $\frac{1}{4} a\sqrt{2}$. Area of one loop $= a^2/2$.

The Helix (Fig. 80) is the curve of a screw thread on a cylinder of radius r. The curve crosses the elements of the cylinder at a constant angle, v. The pitch, h, is the distance between two coils of the helix, measured along an element of the cylinder; hence $h = 2\pi r \tan v$. Length of one coil $= \sqrt{(2\pi r)^2 + h^2} = 2\pi r/\cos v$. To construct the projection of a helix on a plane containing the axis of the cylinder, draw a rectangle, breadth $2r$ and height h, to represent the plane, with a semicircle below it, as in the figure, to represent the base of the cylinder. Divide h into equal parts (here 8), numbered from 1 to 8; think of the circumference as also divided into 8 equal parts, represented on the semicircle by numbers from $1'$ to $4'$ and back again from $4'$ to $8'$. Then the point of intersection of a horizontal line through 1, 2, . . . with a vertical line through $1'$, $2'$, . . . will be a point of the required projection. If the cylinder is rolled out on a plane, the development of the helix will be a straight line, with slope equal to $\tan v$.



Helix.
Fig. 80.

series to protect the alternators and equipment from injury that would result from the tremendous short-circuit currents. For these reasons, poor regulation in large alternators is frequently considered to be an advantage rather than a disadvantage.

TRANSFORMERS

Transformer Theory. The transformer is a device that transfers energy from one electric circuit to another without change of frequency and usually, but not always, with a change in voltage. The energy is transferred through the medium of a magnetic field. The energy is supplied to the transformer through the primary coil; the energy is delivered by the transformer by means of the secondary coil. Both coils link the same magnetic circuit. With no load on the secondary, a small current, called the exciting current, flows in the primary and produces the alternating flux. This flux links both primary and secondary and induces the same volts per turn in each. With a sine wave the emf

$$E = 4.44\,\Phi_m n f 10^{-8} \text{ volts} \tag{90}$$

where Φ_m is the maximum instantaneous flux, n the turns on either winding, and f the frequency. Equation (90) may also be written

$$E = 4.44\,B_m A n f 10^{-8} \text{ volts} \tag{91}$$

B_m is the maximum instantaneous flux density in the iron and A the net cross section of the iron. B_m is practically fixed. In large transformers with silicon steel it varies between 60,000 and 75,000 lines per sq in. at 60 cycles, and between 75,000 and 90,000 lines per sq in. at 25 cycles. It is desirable to operate the iron at as high density as possible in order to minimize the weight of iron and copper. On the other hand, with too high densities the eddy-current and hysteresis losses become too great, and with low frequency the exciting current may become excessive. It follows from Eq. (90) that

$$E_1/E_2 = n_1/n_2 \tag{92}$$

where E_1 and E_2 are the primary and secondary emfs and n_1 and n_2 are the primary and secondary turns. Since the impedance drops in the ordinary transformers are small, the terminal voltages of primary and secondary are also practically proportional to their number of turns. As the change in voltage in the ordinary constant-potential transformer over its range of operation is small (1.5 to 3 percent), the flux must remain substantially constant and the exciting current must remain substantially constant. Therefore, the added ampere-turns produced by any secondary load must be balanced by opposite and equal primary ampere-turns. Since the exciting current is small compared with the load current (1.5 to 8 percent) and the two are usually out of phase, the exciting current may ordinarily be neglected. Hence,

$$n_1 I_1 = n_2 I_2 \quad (93); \qquad \text{and } I_1/I_2 = n_2/n_1 \quad (94)$$

where I_1 and I_2 are the primary and secondary currents.

When load is applied to the secondary of a transformer, the secondary ampere-turns reduce the flux slightly. This reduces the counter emf of the primary, permitting more current to enter and thus supply the increased power demanded by the secondary.

Both primary and secondary coils must necessarily have resistance. All the flux produced by the primary does not link the secondary; the back ampere-turns of the secondary produce some flux which does not link the

may, however, deliver mechanical power and at the same time take either leading or lagging current. Its common applications are drives for motor-generator sets, ammonia compressors in refrigerating plants, rubber mills, and air compressors. The motor should not be used where fluctuations of torque are too violent. As a rule, it should not be used in small sizes (under 50 hp) since it requires d-c excitation, is more difficult to start than induction motors, and falls out of step quite readily when system disturbances occur.

If situated near an inductive load the motor may be overexcited, and its leading current will neutralize entirely or in part the lagging quadrature current of the load. This reduces the I^2R loss in the transmission lines and also increases the kilowatt ratings of the system apparatus. **The synchronous condenser and motor can also be used to control voltage** and to stabilize power lines. If the condenser or motor is overexcited, its leading current flowing through the line reactance causes a rise in voltage at the motor; if it is underexcited, the lagging current flowing through the line reactance causes a drop in voltage at the motor. Thus within limits it becomes possible to control the voltage at the end of a transmission line by regulating the fields of synchronous condensers or motors. Long 220-kv lines and the 287-kv Boulder Dam–Los Angeles line require several thousand kva in synchronous condensers floating at their load ends merely for voltage control. If the load becomes small, the voltage would rise to very high values if the synchronous condensers were not underexcited, thus maintaining nearly constant voltage.

The synchronous motor is started as an induction motor through the action of a starting or damper winding similar to the squirrel-cage rotor winding of an induction motor. Copper or alloy bars are inserted in the faces of the salient d-c field poles, and their ends are brazed to copper segmental end-rings bolted together to form a continuous ring. The process of starting a synchronous motor is simply one of accelerating the motor to as high a speed as it will reach as an induction motor with its damper winding and then applying field excitation in order to pull the rotor into synchronism. Because of its

primary. These leakage fluxes produce reactance in each winding. The combined effect of the resistance and reactance produces an impedance drop in each winding when current flows. These impedance drops produce a slight drop in voltage with load.

Transformer Testing. Transformer regulation and losses are so small that it is far more accurate to compute the regulation and efficiency than to determine them by actual measurement. The necessary measurements and computations are comparatively simple, and little power is involved in making the tests. In the **open-circuit** test, the power input to either winding is measured at its rated voltage. Usually it is more convenient to make this test on the low-voltage winding, particularly if it is rated at 110, 220, or 550 volts. The open-circuit power practically all goes to supply the core losses, consisting of eddy-current and hysteresis losses. Let this value of power be P_0. The eddy-current loss varies as the square of the voltage and frequency; the hysteresis loss varies as the 1.6 power of the voltage, and directly as the frequency (see p. 1704). In the **short-circuit** test one winding is short-circuited, and the current in the other is adjusted to near its rated value. The voltage V_c, the current I_1, and the power input P_c are measured. When one winding of a transformer is short-circuited, the voltage across the other winding is 3 to 4 percent of rated value when rated current flows. Since a voltage range of from 110 to 250 volts is best adapted to measuring instruments, that winding whose rated voltage, multiplied by 0.03 or 0.04, is closest to this voltage range should be used for making the short-circuit test, the other winding being short-circuited. Practically all the power on short circuit goes to supply the copper loss of primary and secondary. If the measurements are made on the primary,

$$R_{01} = P_c/I_1^2 \quad (95); \qquad Z_{01} = V_c/I_1 \quad (96); \qquad X_{01} = \sqrt{Z_{01}^2 - R_{01}^2} \quad (97)$$

where R_{01}, Z_{01}, and X_{01} are the equivalent resistance, impedance, and reactance referred to the primary. Also $R_{02} = R_{01}(n_2/n_1)^2$; $Z_{02} = Z_{01}(n_2/n_1)^2$; $X_{02} = X_{01}(n_2/n_1)^2$, these quantities being the equivalent resistance, impedance, and reactance referred to the secondary. If the d-c resistances, R_1 and R_2, of the primary and secondary are measured,

$$R_{01} = R_1 + (n_1/n_2)^2R_2 \quad (98); \qquad R_{02} = R_2 + (n_2/n_1)^2R_1 \quad (99)$$

The a-c or effective resistances are usually 10 to 15 percent greater than these values.

Regulation. The regulation may be computed from the foregoing data as follows:

$$V_1' = \sqrt{(V_1 \cos\theta + I_1R_{01})^2 + (V_1 \sin\theta \pm I_1X_{01})^2} \qquad (100)$$

$$\text{Regulation} = 100(V_1' - V_1)/V_1 \qquad (101)$$

V_1 = rated primary terminal voltage; $\cos\theta$ = load power factor; I_1 = rated primary current; R_{01} = equivalent resistance referred to primary; X_{01} = equivalent reactance referred to primary. The (+) sign is used with lagging current and the (−) sign with leading current. Equations (100) and (101) are equally applicable to the secondary if the subscripts are changed.

Efficiency. The only two losses in a constant-potential transformer are the core loss in watts P_0 which is practically independent of load and P_c the copper loss in watts which varies as the load current squared. The efficiency for any current I_1 is

$$\eta = V_1I_1 \cos\theta/(V_1I_1 \cos\theta + P_0 + I_1^2R_{01}) \qquad (102)$$

salient poles, the synchronous motor usually pulls into synchronism without d-c field excitation.

As with the larger sizes of induction motors, synchronous motors are usually started at reduced voltage, a compensator (Fig. 62) ordinarily being used. Sometimes the stator winding is connected in Y at starting and in Δ when running. In order to minimize line disturbances, the field is ordinarily connected while reduced voltage is being applied to the stator, and the connection to the running position is made quickly so that the motor does not have opportunity to drop out of step. All starting functions may be automatically performed by the operation of relays.

It is possible to design synchronous motors for any required values of starting and pull-in torque and, by special methods, meet the low-starting inrush current limitations imposed by power companies.

Synchronous Converter

The synchronous converter is essentially a d-c generator with slip rings connected by taps to equidistant points in the armature winding. Hence alternating current may also be taken from and delivered to the armature. The machine may be single-phase, in which case there are two slip rings and two slip-ring taps per pair of poles; it may be three-phase, in which case there are three slip rings and three slip-ring taps per pair of poles, etc. Converters are usually used to convert alternating to direct current, in which case they are said to be operating **direct**; they may equally well convert direct to alternating current, in which case they are said to be operating **inverted**. A converter will operate satisfactorily as a d-c motor, a synchronous motor, a d-c generator, an alternator, or it may deliver direct and alternating current simultaneously when it is called a **double-current generator**.

The rating of a converter increases very rapidly with increase in the number of phases owing, in part, to better utilization of the armature copper and also because of more uniform distribution of armature heating.

Table 17. Relative Outputs of Converter

Power factor, percent	Continuous-current generator	Single-phase converter	Three-phase converter	Four-phase converter	Six-phase converter
100	100	85	132	161	194
95.5	100	78	120	145	170
90	100	74	109	128	145

Because of the materially increased rating, converters are nearly all operated six-phase. The rating decreases rapidly with decrease in power factor, and hence the converter should operate near unity power factor (see Table 17). The diametrical a-c voltage is the a-c voltage between two slip-ring taps 180 electrical degrees apart. With a two-pole closed winding, that is, a winding that closes on itself when the winding is completed, the diametrical a-c voltage is the voltage between any two slip-ring taps diametrically opposite each other.

With a sine-voltage wave, the d-c voltage is the peak of the diametrical a-c voltage wave. The voltage relations for sine waves are as follows: d-c volts, 141; single-phase (diametrical), 100; three-phase, 87; four-phase, diametrical, 100; four-phase, adjacent taps, 71; six-phase, diametrical, 100; six-phase, adjacent taps, 50. These relations are obtained from the sides of polygons inscribed in a circle having a diameter of 100 volts, as shown in Fig. 64.

Equation (102) applies equally well to the secondary if the subscripts are changed. The maximum efficiency occurs when the core and copper losses are equal.

All-day Efficiency. Since transformers must usually be on the line 24 hr per day, part of which time the load may be very light, the all-day efficiency is important. This is equal to the total energy or watthour output divided by the total energy or watthour input for the 24 hr. That is,

$$\eta = \frac{(V_1 I_1 \cos \theta_1)t_1 + \cdots}{(V_1 I_1 \cos \theta_1)t_1 + \cdots + (I_1^2 R_{e1})t_1 + \cdots + 24P_0} \tag{103}$$

where t_1 is the time in hours that load $V_1 I_1 \cos \theta_1$ is being delivered, etc.

Polyphase Transformer Connections. Three-phase transformer banks may be connected Δ-Δ, Δ-Y, Y-Y, and Y-Δ. The Δ-Δ connection is very common particularly at the lower voltages and has the important advantage that the bank will operate V-connected if one transformer is disabled. The Δ-Y connection is advantageous for stepping up to high voltages since the secondary of the transformers need be wound only for 58 percent ($1/\sqrt{3}$) the line voltage; it is also necessary when a four-wire three-phase system is obtained from a three-wire three-phase system since "a floating neutral" on the secondary cannot occur. The Y-Y system may be used for stepping up voltage. It should not be used for obtaining a three-phase four-wire system from a three-phase three-wire system, because of the "floating neutral" on the secondary and the resulting high degree of unbalance of the secondary voltages. The Y-Δ system may be used to step down high voltages, the reverse of the Δ-Y connection. In the Δ-Y and Y-Δ systems the ratio of line voltages is obviously not that of the individual transformers. Because of different phase displacement between primaries and secondaries, a Δ-Δ bank cannot be connected in parallel (on both sides) with a Δ-Y bank, etc., even if they both have the correct voltage ratios between lines (see p. 1713).

Three-phase transformers combine the magnetic circuits of three single-phase transformers so that they have parts in common. A material saving in cost, in weight, and in space results, the greatest saving occurring in the case and oil. The advantages of three-phase transformers are often outweighed by their lack of flexibility. The failure of a single phase shuts down the entire transformer. With three single units, one unit may be readily replaced with a single spare. The primaries of single-phase transformers may be connected in Y or Δ at will and the secondaries properly phased. The primaries, as well as the secondaries of three-phase transformers, must be phased.

For the transformation of moderate amounts of power from three-phase to three-phase, two transformers employing either the V- or the **T-connection** (Fig. 59) may be used. The ratings of these systems are only 58 percent of the rating of the system using three similar transformers, one for each phase.

To transform from two- to three-phase or the reverse, the **T-connection** (Fig. 60) is used. To make the secondary voltages symmetrical a tap (called a **Scott tap**) is brought out at 87 percent ($\sqrt{3}/2$) of the primary winding of the auxiliary transformer as shown in Fig. 60. With balanced no-load voltages the voltages become slightly unbalanced even under a symmetrical load, owing to unequal phase differences in the individual coils. The three-phase neutral 0 is one-third the distance along the auxiliary transformer from the junction (see also pp. 1713, 1714).

At unity power factor and 100 percent efficiency, the ratio of alternating to direct current is as follows: 2 slip rings, 1.41; 3 slip rings, 0.94; 4 slip rings, 0.71; 6 slip rings, 0.47. At efficiency η and power factor p.f., divide by these quantities. Twenty-five cycle converters are slightly more efficient than 60-cycle converters.

The d-c voltage of converters may be controlled a limited amount by varying the field excitation. This, however, changes the power factor simultaneously. Converters are compounded. In split-pole converters, the space distribution of the field magnetism is altered by subdividing the field poles into two or three sections. By varying the ampere-turns of the sections the wave form and ratio of transformation may be varied to a limited extent. With large units, the most satisfactory method is to use an alternator of smaller rating and of the same number of poles mounted on the same shaft. This alternator, called a **booster**, may boost or buck the converter voltage. Converters operate satisfactorily in parallel. When used to convert alternating to direct current, the machine must be in synchronism with the alternating supply. The converter may be started from the a-c end in much the same manner that synchronous motors are started. Occasionally the machine is brought to speed as a d-c motor and synchronized. When operated inverted (direct current to alternating current) some centrifugal or electrical device must be employed to prevent the converter from running away since a highly inductive load weakens the field through armature reaction and causes the speed to increase.

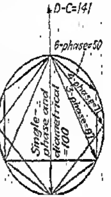

FIG. 64.—EMF Relations in Converter.

Converters are cheaper, more efficient, and occupy less floor space than motor-generator sets. They are much less flexible in the matter of voltage and power-factor control. Where they cannot operate near unity power factor and where otherwise transformers are not necessary, their advantage over a motor-generator set is doubtful.

Industrial synchronous converters have efficiencies at one-half (full) load from 90 to 92.5 (92.4 to 94.3) percent, the larger sizes having the higher efficiencies. Synchronous booster efficiencies at one-half (full) load vary similarly from 91.3 to 93 (93.8 to 94.4) percent (see also Fig. 67).

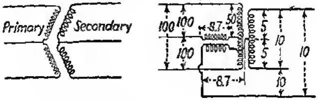
For the conversion of alternating to direct current at 600 volts (d-c) and higher, mercury-arc metal-tank rectifiers, rather than motor-generator sets and synchronous converters, are being used in new installations (see p. 1753).

Rating of Electrical Apparatus

The rating of electrical apparatus is almost always determined by the maximum temperature at which the materials in the machine, especially those employed for insulation, may be operated for long periods without deterioration. It is permissible, as far as temperature is concerned, to overload the apparatus so long as the safe temperature is not exceeded. The A.I.E.E. Standards, No. 5, July, 1925, classify **insulating materials** in three general classes: Class O—cotton, silk, paper, and similar organic materials when neither impregnated nor immersed in oil; Class A—cotton, silk, paper, and similar organic materials when so treated or impregnated as to increase the thermal limit, or when permanently immersed in oil, and also enameled wire; Class B—inorganic materials such as mica and asbestos in built-up form combined with binding substances.

The limiting temperature rises are as follows: Class O—no agreement reached but maximum temperatures should not exceed 100 C. Class A—(1) armature windings, wire field windings and all windings other than (2), 55 C; (2) single-layer field windings with exposed uninsulated surfaces and bare copper windings, 65 C; (3) cores and mechan-

An autotransformer, also called compensator or balancing coil, consists essentially of a single coil linking a magnetic circuit. Part of the energy is transformed, and the remainder flows through conductively. Suitable taps are provided so that, if the primary voltage is applied to two of the



V-connection. T-connection.

FIG. 59.—Transformer Connections for Transforming Moderate Amounts of Three-phase Power.

taps, a voltage may be taken from any other two taps. The ratio of voltages is equal practically to the ratio of the turns between their taps. An autotransformer should be installed only when the ratio of transformation is not large. The ratio of power transformed to total power is $1 - n$, where n is the

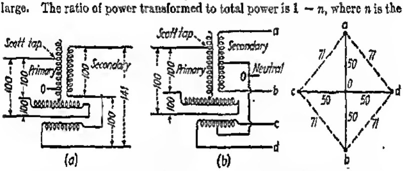


FIG. 60.—Connections for Transforming from Three-phase to Two- and Four-phase.

ratio of low-voltage to high-voltage emf. This gives the saving over the ordinary transformer and is greatest when the ratio is not far from unity. Figure 61(*a*) shows 100 kw being changed from 3,300 to 2,300 volts; 30.3 kw only are being actually transformed, and the remainder of the power flows through

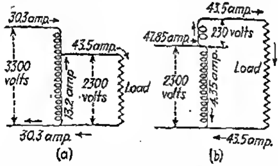

FIG. 61.—Autotransformer.

conductively. Figure 61(*b*) shows how an ordinary 10:1, 10-kw lighting transformer may be connected to boost 110 kw 10 percent in voltage. In Fig. 61(*b*), however, the 230-volt secondary must be insulated for 2,300 volts to the core and ground. The voltage may likewise be reduced by reversing

ical parts in contact with or adjacent to insulation, 55 C; (4) commutators and collector rings, 65 C. Class B—all temperatures 20 C higher than Class A. The temperature measurements are determined with a thermometer. Ordinarily an ambient temperature of 40 C is used.

Efficiency of Electrical Apparatus

The losses in electrical apparatus are iron losses, copper or I^2R losses, and, where there are revolving parts, friction losses. In constant-speed machinery or machinery operating under constant voltage as is generally the case, the iron losses are nearly constant regardless of load. The copper losses are proportional to the square of the load current. To determine the efficiency of electrical apparatus the output and input are sometimes measured. This is frequently impracticable, and the method is open to the objection that it is difficult to measure mechanical input or output accurately. A more accurate and satisfactory method is to measure the electrical input or output, depending on whether the machine is motor or generator, and calculate the losses.

In a motor or generator, the constant losses are hearing and brush friction, windage, armature hysteresis and eddy-current losses (called stray power), and the field copper losses. The stray power may be determined very closely by running the machine light, whether motor or generator, at the same induced emf and speed as under load conditions and measuring the armature input. From the measured resistance of the armature (including brushes and brush-contact resistance) the armature $I_a^2R_a$ losses may be calculated for any assumed output or input. If the machine is a motor, the output is

$$(\text{Input} - \text{losses}) = VI - I_a^2R_a - VI_f - S_p \qquad (109)$$

where V is the terminal voltage, I the line current, I_f the shunt-field current, and S_p the stray power. Since I includes the field current I_f,

$$\text{Output} = VI_a - I_a^2R_a - S_p \qquad (110)$$

With a generator,

$$\text{Input} = (\text{output} + \text{losses}) = VI + I_a^2R_a + VI_f + S_p \qquad (111)$$

The efficiency η = (input − losses)/input = output/(output + losses) may be calculated from Eqs. (109), (110), and (111). Since shunt motors are frequently used to drive pumps, compressors, and similar apparatus, Eq. (110) is very useful in determining their outputs (see pp. 1724 and 1727 for the efficiencies of generators and motors).

Industrial Applications of Motors

Alternating or Direct Current. The induction motor, particularly the squirrel-cage type, is preferable to the d-c motor for constant-speed work, for the initial cost is less and the absence of a commutator reduces maintenance. Also there is less fire hazard in many industries, such as saw mills, textile mills, and powder mills. The use of the induction motor in such places as cement mills is advantageous since with d-c motors the grit makes the maintenance of commutators difficult.

For variable-speed work like cranes, hoists, elevators, and for adjustable speeds, the d-c motor characteristics are superior to induction-motor characteristics. Even then, it may be desirable to use induction motors since their less desirable characteristics are more than balanced by their simplicity and the fact that a-c power is available. Direct-current power is supplied at 115 and 230 volts, 230 volts being preferable because of the saving in copper. In certain railway shops where 550 volts is available, 550 volt motors may be used, but their use, particularly in small sizes, is undesirable because of com-

the 230-volt coil. An autotransformer should never be used when it is desired to keep dangerous primary potentials from the secondary. It is used for starting induction motors (Fig. 62) and for a number of similar purposes.

Data on Transformers. Single-phase 55-deg self-cooled oil-insulated transformers for 2,300 volt primaries, 230—115-volt secondaries, and in sizes from 5 to 200 kva for 60(25) cycles have efficiencies from one-half to full load of about 98 (97–98.7) percent and regulation of 1.5 (1.1 to 2.1) percent with p.f. = 1, and 3.5 (2.7 to 4.1) percent with p.f. = 0.8. Power transformers with 13,200-volt primaries and 2,300-volt secondaries in sizes from 667 to 5,000 kva and for both 60 and 25 cycles have efficiencies from one-half to full load of about 99.0 percent and regulation of about 1.0 (4.2) percent with p.f. = 1(0.8).

Alternating-current Motors

Polyphase Induction Motor. The polyphase induction motor is the most common type of motor used. It ordinarily consists of a stator which is wound in the same manner as an alternator stator. If two-phase current is supplied to a two-phase winding or three-phase current to a three-phase winding, a rotating magnetic field is produced in the air gap. The number of poles which this field has is the same as the number of poles that an alternator employing the same stator winding would have. The speed of the rotating field, or the *synchronous speed*,

$$N = 120f/P \text{ rpm} \qquad (104)$$

where f is the frequency and P the number of poles.

There are two general types of rotors. The **squirrel-cage type** consists of heavy copper bars short-circuited by end rings, or the bars and end rings may be an integral aluminum casting. The **wound rotor** has a polyphase winding of the same number of poles as the stator, and the terminals are brought out to slip rings so that external resistance may be introduced. The rotor conductors must be cut by the rotating field, hence the rotor cannot run at synchronous speed but must slip. The *slip*, $s = (N - N_2)/N$ (105) where N_2 = the rotor rpm. The rotor frequency

$$f_2 = sf \qquad (106)$$

The torque is proportional to the air-gap flux and the components of rotor current in space-phase with it. The rotor currents tend to lag the emfs producing them, because of the rotor-leakage reactance. From Eq. (106) the rotor frequency is low when the motor is running near synchronous speed, and hence there is a large component of rotor current in space-phase with the flux. With large values of slip the increased rotor frequency increases the lag of the rotor currents behind their emfs, and hence considerable space-phase difference between these currents and the flux develops. Therefore, even with large values of current the torque may be small. The torque of the induction motor increases with slip until it reaches a maximum value called the **breakdown torque**, after which the torque decreases (see Fig. 63). The breakdown torque varies as the square of the voltage, inversely as the stator impedance and rotor reactance, and is independent of the rotor resistance.

The squirrel-cage motor develops but little torque on starting ($s = 1.0$) even though the current may be three to seven times rated current. For any value of slip the torque of the induction motor varies as the square of the voltage. The torque of the squirrel-cage motor on starting is inherently low

mutator difficulties. Alternating current is almost always 60 cycles, three-phase, and 220, 440, and 550 volts are all used for smaller motors. For larger motors, 1,150, 2,300, and even 6,600 volts may be used. Where both lights and motors are to be supplied from the same a-c system, the 208–120 volt four-wire three-phase system is now in common use. This gives 208 volts 3-phase for the motors, and 120 volts to neutral for the lights.

Electric Drives

Cranes and Hoists. The d-c series motor is best adapted to cranes and hoists. When the load is heavy the motor slows down automatically and develops increased torque thus reducing the peaks on the electrical system. With light loads, the speed increases rapidly, thus giving a lively crane. The series motor is also well adapted to moving the bridge itself and also the trolley along the bridge. Where alternating current only is available and it is not economical to convert it, the slip-ring type of induction motor, with external-resistance speed control, is the best type of a-c motor. Squirrel-cage motors with high-resistance end rings to improve the starting torque are used occasionally (also see Ilgner system, p. 1730).

Woodworking Machinery. Circular saws are usually driven by a belted squirrel-cage induction motor running at 1,140 and 1,720 rpm, the speeds of the saws being much greater than those of the motors. **Band saws** have considerable flywheel effect and require motors having high starting torque. Slip-ring motors may be used, but squirrel-cage motors having 7 to 8 percent slip are desirable. An added advantage is the fact that with heavy load, the motor slows down, thus utilizing the flywheel energy of the saw. **Planers** may be driven at high speed by belted squirrel-cage induction motors. In modern practice the motor is an integral part of the machine, using direct drive. Since speeds of 6,000 to 10,000 rpm are necessary and at 60 cycles the maximum speed obtainable is 3,600 rpm, the two-pole motors are supplied at higher frequencies by frequency changers. This is economical only with a number of planers.

Pumps. Single-acting **reciprocating pumps** should be driven with compound motors and duplex and triplex pumps with shunt motors, if direct current is used. Squirrel-cage and slip-ring motors are satisfactory with a-c supply. To reduce starting torque a by-pass in the pump is frequently opened until the motor comes up to speed. Constant head requires constant torque, and variable capacity under these conditions necessitates variable speed. For efficient operation, field control should be used with d-c motors and pole changing with induction motors.

Centrifugal pumps may be driven by shunt, compound, squirrel-cage, and slip-ring motors. Since such pumps require very small starting torque, general-purpose squirrel-cage motors make an ideal drive.

Compressors may be driven with shunt, squirrel-cage, slip-ring, and synchronous motors. With 100 hp and greater, direct connection is preferable. Many types of compressors require flywheel effect, particularly with synchronous-motor drive. Synchronous motors are being widely used for compressor drive because of their desirable power-factor characteristics. High-torque synchronous motors have been developed which can replace most induction motors of 50 hp and greater.

Rectifiers

Direct current is frequently necessary for such purposes as electric railways, electrolytic work, and charging batteries, when only alternating current is available. With large amounts of power either induction or synchronous motor-generator-sets or synchronous converters and also mercury-arc rectifiers may be used for converting the power. For small amounts of power, rectifiers are, as a rule, less expensive and more efficient.

With a single rectifier unit [Fig. 65(a)] the negative half-wave is eliminated entirely, and, with a noninductive load, current flows only on alternate half-cycles [Fig. 65(b)]. This is called **half-wave** rectification. With two rectifier units and a center-tap connection o in the secondary of the trans-

but is still further reduced in the larger motors because of the necessity for applying reduced voltage.

Polyphase squirrel-cage motors are used for constant-speed work. They are being used more commonly on account of their rugged construction and the absence of moving electrical contacts which makes them suitable for operation when exposed to inflammable dust or gas. General-purpose squirrel-cage motors have starting torques of about 1.5 times full load torque at rated voltage. The highest torques occur at the higher rated speeds. The locked rotor currents vary between four and seven times full-load current. Special motors with high-resistance rotors are built up to approximately 50 hp usually for intermittent duty on elevators, punch presses, and similar applications. These generally give the maximum torque at starting and operate at approximately 15 to 20 percent below synchronous speed at full load. They give rapid acceleration, and their starting current is relatively low. Up to 7.5 hp, the squirrel-cage motor may usually be connected directly across the line. If the motor is protected from overload by fuses, a double-throw switch should be used so that the large starting current does not flow in the fuses. In modern practice, motors are protected by temperature overload relays which operate thermally to trip the circuit breaker. Since a time element is involved in the operation of such relays, they do not respond to large starting currents, because of their short duration.

By some modifications in conventional design, motors as large as 200 hp can be connected directly across the line without the current exceeding 3.5 times rated current. A **double-squirrel-cage motor** is an example. In this type of motor there is a high-resistance winding in the top of the rotor slots and a low-resistance winding in the bottom of the slots. The low-resistance winding is made to have a high leakage reactance, either by separating the windings with a magnetic bridge or by making the slot very narrow in the area between the two windings. On starting, because of the high reactance of the low-resistance winding, most of the rotor current will flow in the high-resistance winding, giving the motor a large starting torque. As the rotor approaches the low value of slip at which it normally operates, the rotor frequency and hence the rotor reactance become low and most of the rotor current flows in the low-resistance winding. Hence the motor operates with a low value of slip. It thus has the excellent operating characteristics of the single-squirrel-cage motor and at the same time has a large starting torque.

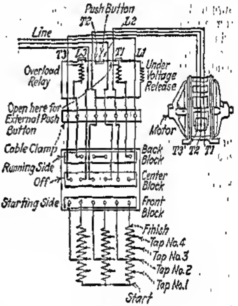

FIG. 62.—Connections of General Electric Compensator.

In order to reduce the line current in the larger ratings a polyphase **auto-transformer or compensator** is used (Fig. 62). On starting, the three

former [Fig. 66(a)], current can flow to the positive terminal of the load through unit 1 when terminal a is positive and, likewise, through unit 2 to the positive terminal of the load when terminal b is positive. This gives **full-wave** rectification [Fig. 66(b)]. If a smoothing inductance is connected in series with the load, the current is prevented from going to zero by the inertia effect of the inductance, and the pulsations in the rectified wave become small ripples [Fig. 66(c)].

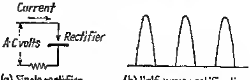

FIG. 65.—Single Rectifier Unit and Half-wave Rectification.

Full-wave rectification without a center tap may be obtained by means of the **bridge circuit** (Fig. 67). Four rectifying units are connected to form four bridge arms ab, ac, bd, and cd as shown. When line $a'a$ is positive, the current path is a, b; load, c, d. When line $d'd$ is positive, the current path is d, b; load, c, a. Current thus always enters the load at the positive terminal. The same full wave as shown in Fig. 66(b) will thus be obtained, and smoothing inductance may be used to reduce the current pulsations as in Fig. 66(c).

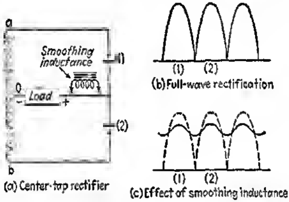

FIG. 66.—Two Rectifier Units and Center-tap Connection.

The **mercury-arc rectifier** depends on the rectifying action of mercury vapor for its operation. Figure 68 shows a typical single-phase rectifier. The glass tube is exhausted to a vacuum of 0.001 to 0.0005 mm. The iron cathode C is in contact with a pool of mercury. The anodes A_1 and A_2 are graphite. Current enters anodes A_1 and A_2 during alternate half-cycles, flows to the cathode and out to the load. Inductance in series with the load is necessary to prolong the current flow beyond the half-cycle of voltage and thus maintain the arc. The rectifying action is due to the fact that the arc maintains the cathode hot spot in the pool of mercury, making it a source of high electron emission. The electrons are attracted to each anode as it becomes positive and result in current flow from anode to cathode during this time. The direction of current flow is opposite to the direction of flow of the electrons. A starting anode A_3 in series with resistance R is necessary to start the arc. Figure 69 shows a three-phase rectifier being supplied by three secondaries of a three-

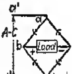

FIG. 67.—Bridge Circuit for Full-wave Rectification.

coils are connected in Y across the line, and the motor is connected across the taps which reduce voltage at the motor terminals. A double-throw switch is so arranged that the motor, after it has been started, can be connected across the full line potential and the autotransformer disconnected from circuit. The double-throw switch, which is equipped with sliding, self-wiping contacts, is immersed in oil. Means are provided for preventing the switch being thrown to the running position without first being thrown to the starting position. The taps are generally brought out from the windings so as to give voltages of approximately 40, 58, 70, and 80 percent of line voltage. To limit the current to as low a value as possible, the lowest taps that will give the motor sufficient voltage to supply the required starting torque should be used. *As the torque of an induction motor varies as the square of the voltage*, the compensator produces a very low starting torque.

Resistances in series with the stator may also be used to start squirrel-cage motors. They are inserted in each phase and are gradually cut out as the motor comes up to speed. The resistors are generally made of wire-type resistance units or of graphite disks inclosed within heat-resisting porcelain-lined iron tubes. The disadvantage of resistors is that if the motor is started slowly the resistor becomes very hot and may burn out. Resistor starters are less expensive than autotransformers. Their application is to motors that start with light loads at infrequent intervals.

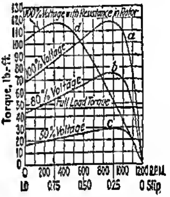

Fig. 63.—Speed-torque Curve of 10-hp, 60-cycle, 1140-rpm Induction Motor. Curves (*a*), (*b*), (*c*)—Squirrel-cage Characteristics; Curve (*d*) Resistance in Wound-rotor Motor.

By introducing resistance into the rotor circuit through slip rings, the rotor currents may be brought nearly into phase with the air-gap flux and, at the same time, any value of torque up to maximum torque obtained. As the rotor develops speed, resistance may be cut out until there is no external resistance in the rotor circuit. The speed may also be controlled by inserting resistance in the rotor circuit. However, like the armature-resistance method of speed control with shunt motors (see p. 1729), *it is inefficient and gives poor speed regulation.* Figure 63 shows graphically the effect on the torque of introducing resistance into the rotor circuit. The wound-rotor motor is used where large starting torque is necessary as in railway work, hoists, and cranes. It has better starting characteristics than the squirrel-cage motor, but, because of the necessarily higher resistance of the rotor, it has greater slip even with the rotor resistance all cut out. Obviously, the wound rotor, controller, and external resistance make it more expensive than the squirrel-cage type.

One **disadvantage of induction motors** is that they take lagging current and the power factor at half load and less is low. The speed-load and torque-load characteristics of induction motors are almost identical with those of the shunt motor. The speed decreases slightly to full load, the slip being from 10 percent in small motors to 2 percent in very large motors. The torque is almost proportional to the load nearly up to the breakdown torque. The power factor is 0.8 to 0.9 at full load. The direction of rotation of any three-phase motor may be reversed by interchanging any two stator wires.

Speed Control of Induction Motors. The induction motor inherently is a constant-speed motor. From Eqs. (104) and (105) the rotor speed

phase transformer system. Current enters the tube at any of the three graphite electrodes A, A', A'', and leaves at the cathode C. *Multiphase rectifiers require no inductance to sustain the* arc, although a smoothing inductance (Fig. 69) is usually connected in the load circuit to eliminate the current ripples. Single-phase glass-tube units are available up to 50 amp at 110 volts. The voltage drop across the arc is nearly constant at approximately 25 volts, irrespective of current, so that the efficiency of mercury arcs increases with voltage.

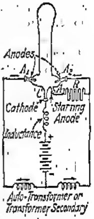

FIG. 68.—Single-phase Mercury-arc Rectifier.

Mercury-arc rectifiers with metal tanks for supplying large amounts of power have been developed. These usually operate six-phase. They are built in units of 300 kw at 250 volts up to 3,000 kw at 600 volts and to 4,000 kw at 3,000 volts and have been used successfully for street-railway and other d-c power supply. At 600 volts and over, they compare very favorably with the synchronous converter (see Fig. 70).

For 600 volts and higher the anodes, usually 6, 12, or 18 *in number, are mounted within a single tank and a single* mercury pool constitutes the common cathode. The voltage drop from anode to cathode is from 20 to 25 volts and does not vary with the current but remains nearly constant. Hence the efficiency increases with increase in voltage. At 250 volts the stated values of voltage drop would give an efficiency in the neighborhood of 90 percent. To decrease the voltage drop the **ignitron** is used for the lower voltages. Each anode and its cathode are mounted within a single steel tank; the cathode is not usually insulated from the tank. The single tank permits much closer spacing of anode and cathode and reduces the voltage drop. The arc is ignited each half-cycle by a high-resistance rod *which dips into the mercury pool*, the rod being energized at the proper instant. Its action is not unlike that of a spark plug.

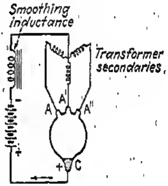

FIG. 69.—Three-phase Mercury-arc Rectifier.

Figure 70 shows the over-all efficiencies of metal-tank rectifiers, a synchronous converter, and a synchronous motor-generator set. All units have the same power rating of 3,000 kw; the losses in the transformers and auxiliary equipment are included.

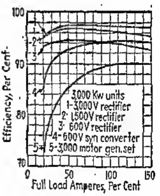

FIG. 70.—Comparative Efficiencies of Converting Machinery.

The **Tungar rectifier** consists of a glass bulb filled with inert argon gas at low pressure, a tungsten filament which can be heated and used as a cathode, and an additional graphite electrode which is the anode (Fig. 71). This rectifier operates on the principle of electron emission and ionization by collision. *When the anode is positive with respect to the filament, electrons* emitted by the hot filament are attracted to the anode and ionize, by collision, the molecules of the gas. The negative ions go to the anode and the positive

$$N_2 = 120f(1 - s)/P \tag{107}$$

The speed can be changed only by changing the frequency, poles, or slip. In some applications where the motors constitute the only load on the alternators, as with electric propulsion of ships, their speed may be changed by changing the frequency. Even then the range is limited, for both turbines and alternators must operate near their rated speeds for good efficiency. By employing two distinct windings or by reconnecting a single winding by switching it is possible to change the number of poles. Complications prevent more than two speeds being readily obtained in this manner. Elevator motors frequently have two distinct windings, and in the U. S. S. "Tennessee" the motors also have two windings, one wound for 24 and the other for 36 poles. In the U. S. S. "New Mexico" the windings are reconnected for 24 and 36 poles by switching. Another objection to changing the number of poles is the fact that the design is a compromise, and sacrifices of desirable characteristics usually are necessary at both speeds.

Table 15. Induction Motor Data
(Westinghouse Electric & Mfg. Co.)
Three phase, 220 volt, 60 cycle, 1,750 rpm

Horse power	Weight, lb	Amp	Power factor, percent			Efficiency, percent		
			½ load	¾ load	4/4 load	½ load	¾ load	4/4 load

1,000	8,450	212	90.0	92.8	93.5	92.2	93.4	94.0

(See Table 22, p. 1764 for the approximate full-load currents of motors.)

ions to the filament, current flow thus being from anode to filament. During the next half-cycle when the filament is positive with respect to the anode, the electrons are attracted into the filament, ionization ceases, and no current flows. Such rectifiers have a maximum rating of 75 volts and 6 amp, and the efficiency is 70 percent approximately. They are used extensively for charging storage batteries.

Electrolytic rectifiers consist of an aluminum plate and a lead plate immersed in ammonium phosphate or sodium borate solution. Current can pass from the lead plate, but not from the aluminum to the solution. By using an aluminum plate on each side of the lead and connecting the load between the lead plate and the center of the transformer winding, full-wave rectification is obtained.

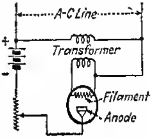

FIG. 71.—Connections for Tungar Rectifier.

The **copper oxide** or **Rectox** rectifier operates on the principle that a layer of cuprous oxide on the surface of copper permits the passage of electrons from the copper to the oxide but prevents their passage in the opposite direction. The conventional direction of current flow is opposite that of the electrons. In the commercial rectifier, the units consist of washers 1⅛ to 1½ in. diam, mounted on an insulating rod. A soft metal washer is placed between copper washers to produce a more uniform pressure on the oxide. The connections are shown in Fig. 72, the "bridge circuit" (Fig. 67) being used since it gives full-wave rectification. This type of rectifier is adapted only to small power and optimum conditions; the efficiency is 70 to 75 percent. Since it is inexpensive and requires negligible maintenance, it is the most widely used rectifier for small amounts of power.

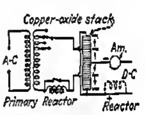

FIG. 72.—Copper-oxide Rectifier with Bridge Circuit.

Switchboards

Switchboards may, in general, be divided into two classes: **direct-control** and **remote-control boards**. With direct-control boards the switches, bus bars, meters, and other apparatus are mounted on or near the board; with remote-control boards, all bus bars, switches, and similar equipment are located some distance from the board, usually in separate compartments or rooms, and only the control-circuit apparatus is on the board. For low-voltage circuits up to and including 750 volts, direct-control panels are generally used. For circuits of 1,100 volts and over, no live switch parts or apparatus should appear on the face of the board and all switches should be of the remote-control type. Most **switchboard panels** are now standardized as to size and thickness. Standard switchboards for central stations are usually 90 in. high, and each panel consists of two or three slabs. The lengths of the General Electric Co. standard slabs for a two-piece panel are 62 and 28 in., respectively, for upper and lower slabs, and the corresponding dimensions for Westinghouse slabs are 65 and 25 in. Marble is still used for switchboard panels, but its use is becoming less common. Slate, which is less expensive than marble, is used extensively and may be made moisture- and oil-proof by black enameling or by finishing in black marine. Rolled sheet metal and ebony asbestos board are used considerably.

The change of slip by introducing resistance into the rotor circuit has been discussed under the wound-rotor motor (see p. 1743). It is possible to introduce counter emfs into the rotor circuit at slip frequency, by means of special commutator machines. The power, which in resistance control is dissipated as heat, is converted into mechanical power and a portion returned to the line. This method of control is only practicable in very large units and its applications are limited. In the **concatenation method** of speed control the rotors of two wound-rotor motors are mechanically coupled together. The stator of the second motor is supplied with power from the rotor slip rings of the first motor. If both motors have the same number of poles and equal number of turns in both stator and rotor, the set will operate efficiently at a little less than half synchronous speed. Because of its complications this method is little used in this country.

Induction Generator. If an induction motor, while connected to a source of power, is driven above synchronous speed, it becomes an **induction, or asynchronous, generator** and returns electrical energy to the line without any change in connections. When driven above synchronous speed, the rotor conductors cut the rotating field in a direction opposite to that when operating as a motor, and hence the mechanical power applied to the shaft is converted into electrical power. The load increases with the negative slip; this permits induction generators to be driven by prime movers without governor control. On short-circuit, the induction generator has the desirable characteristic of not delivering any power. It must always be used in parallel with some synchronous apparatus. Since it must take lagging current from the line for its own excitation, and in addition cannot deliver any lagging current to the system, the induction generator is little used for power supply. Induction motors are frequently used in railway work, especially in mountain systems where it is advantageous on the down-grades to permit the motors to operate as induction generators, thus acting as brakes and in addition returning energy to the line.

Single-phase Induction Motor. If one phase of a three-phase motor is opened while the motor is running, it will continue to operate, but with a rating of only about 60 percent of its three-phase rating. Likewise, if one phase of a two-phase motor is similarly opened, the motor will continue to operate at one-half its two-phase rating. In both cases the motor continues to operate single phase. It will not, however, start single phase. The single-phase motor runs in the direction in which it is started. There are several methods of starting single-phase induction motors. Short-circuited turns, or "shading coils," may be placed around the pole tips which retard the time phase of the flux in the pole tip, and thus a weak torque in the direction of rotation is produced. A high-resistance starting winding placed to produce poles between the main poles provides a rotating field which is weak but is sufficient to start the motor. This is called the "split-phase" method. In order to minimize overheating this winding is ordinarily cut out by a centrifugal device when the armature reaches speed. In the larger motors a repulsion-motor start is used. The rotor is wound like an ordinary d-c armature with a commutator, but with short-circuited brushes pressing on it axially rather than radially. The motor starts as a repulsion motor, developing high torque. When it nears its synchronous speed, a centrifugal device pushes the brushes away from the commutator, and at the same time causes the segments to be short-circuited, thus converting the motor into a single-phase induction motor.

Switchboards should be erected at least 3 or 4 ft from the wall. For panels supplying circuits of 750 volts or less the frames should be insulated from ground, and for higher voltages all frames should be grounded. For low-potential work, the conductors on the rear of the switchboard are usually made up of flat copper strip, known as **bus-bar** copper. The size required is based upon a current density of about 1,000 amp per sq in. Table 18 gives the sizes of horizontal bus bars for various currents. When the current is greater than the values given in the table, a laminated bar is built up of thin strips separated from each other to give a greater radiating surface.

The current-carrying capacity is calculated on the basis of 50 percent load factor for densities which under average conditions of radiation would give a temperature rise of about 10 C. With a load factor of 100 percent the current densities given should be halved. For vertical bus bars the values of current should be reduced 15 to 20 percent.

Equipment of Standard Panels. Following are enumerated the various parts required in the equipment of standard panels for varying services:

Generator or Synchronous-converter Panel, Direct-current Two-wire System: 1 circuit breaker; 1 ammeter; 1 handwheel for rheostat; 1 voltmeter; 1 main switch (3-pole s.t. or d.t.) or 2 s.-p. switches.

Generator or Synchronous-converter Panel, Direct-current Three-wire System: 2 circuit breakers; 2 ammeters; 2 handwheels for field rheostats; 2 field switches; 2 potential receptacles for use with voltmeter; 3 switches; 1 four-point starting switch.

Generator or Synchronous-motor Panel, Three-phase Three-wire System: 3 ammeters; 1 three-phase wattmeter; 1 voltmeter; 1 field ammeter; 1 d.p. field switch; 1 handwheel for field rheostat; 1 synchronizing receptacle (4-pt.); 1 potential receptacle (8-pt.); 1 field rheostat; 1 triple-pole oil switch; 1 power-factor indicator; 1 synchronizer; 2 series transformers; 1 governor-control switch.

Synchronous-converter Panel, Three-phase: 1 ammeter; 1 power-factor indicator; 1 synchronizing receptacle; 1 triple-pole oil circuit breaker; 2 current transformers; 1 potential transformer; 1 watthour meter (polyphase); 1 governor control switch.

Induction Motor Panel, Three-phase: 1 ammeter; series transformers; 1 oil switch.

Feeder Panel, Direct-current, Two-wire and Three-wire: 1 s.-p. circuit breaker; 1 ammeter; 2 s.-p. main switches; potential receptacles (1 four-point for 2-wire panel; 1 four-point and 1 eight-point for 3-wire panel).

Feeder Panel, Three-wire, Three-phase and Single-phase: 3 ammeters; 1 automatic oil switch (3-pole for three-phase, 2-pole for single-phase); 2 series transformers; 1 shunt transformer; 1 wattmeter; 1 voltmeter; 1 watthour meter; 1 handwheel for control of potential regulator.

Exciter Panel (for 1 or 2 exciters): 1 ammeter (2 for 2 exciters); 1 field rheostat (2 for 2 exciters); 1 four point receptacle (2 for 2 exciters); 1 equalizing rheostat for regulator.

Phase Converter. If a polyphase induction motor be operating single-phase, polyphase emfs are generated in its stator. Such a machine can be utilized, therefore, for converting single-phase power into polyphase power and when so used is called a **phase converter.** Unless corrective means are utilized, the polyphase emfs at the machine terminals are somewhat unbalanced. The phase converter is used principally on railway locomotives, for it makes possible the use of three-phase driving motors with but a single trolley wire.

Alternating-current Commutator Motors. Inherently simple a-c motors are not adapted to high starting torques and variable speed and do not have good operating characteristics, particularly with regard to commutation. There are a large number of types of commutating motor that have been developed to meet the requirement of high starting torque and adjustable speed, particularly with single phase. These usually have been accompanied by compensating windings, centrifugal switches, etc., in order to overcome low power factors and commutation difficulties. With proper compensation, commutator motors may be designed to operate at a power factor of nearly unity or even to take leading current.

One of the simplest of the **single-phase commutator motors** is the a-c series railway motor such as is used on the New York, New Haven, and Hartford Railroad. It is based on the principle that the torque of the d-c series motor is in the same direction irrespective of the polarity of its line terminals. This type of motor must be used on low frequency, not over 25 cycles, and is much heavier and more costly than an equivalent d-c motor. The torque and speed curves are almost identical with those of the d-c series motor. Unlike most a-c apparatus the power factor is highest at light load and decreases with increasing load. Such motors operate with direct current even better than with alternating current. **Universal motors** are small simple series motors, usually of fractional horsepower, and will operate on either direct or alternating current, even at 60 cycles. They are used for vacuum cleaners, electric drills, and small utility purposes.

Synchronous Motor. Just as d-c shunt generators operate as motors, an alternator if connected across a-c bus bars to which power is being supplied will operate as a motor if its driving torque is removed, and mechanical power may be delivered by its shaft. Each conductor on the stator must be passed by an alternate pole every half-cycle so that at constant frequency the rpm of the motor is constant and is equal to

$$N = 120f/P \text{ rpm} \qquad (108)$$

and the speed is independent of the load.

The synchronous motor has the desirable characteristic that its power factor can be varied over wide range merely by changing the field excitation. With a weak field the motor takes a lagging current. If the load is kept constant and the excitation increased, the current decreases and the phase difference between voltage and current becomes less until the current is in phase with the voltage and the power factor is unity. The current is then at its minimum value, and the corresponding field current is called the *normal excitation.* Further increase in field current causes the armature current to lead and the power factor to decrease. Thus *underexcitation* causes the current to *lag;* overexcitation causes the current to *lead.* Because of its adjustable power factor, the motor is frequently run light merely to improve power factor or to control the voltage at some part of a power system. When so used the motor is called a **synchronous condenser.** The motor

Switches. The current-carrying parts of switches are usually designed for a current density of 1,000 amp per sq in. At contact surfaces, the current density should be kept down to about 50 amp per sq in. Knife switches are used on low-tension circuits and, in most cases, are mounted on the front of the board. They should be mounted to throw vertically, with the blade

side of the switch dead or disconnected from the source of power when open, to lessen the danger of accidental contact. Plug switches are used on high-voltage circuits where the current is small, as with arc-lighting circuits. **Copper-brush switches** substitute a leaved copper brush with a wiping contact for the knife-blade contact and make use of an auxiliary break between carbon blocks to prevent burning of the copper leaves due to arcing. This type of switch is much used as a circuit breaker, being rendered automatic

DIFFERENTIAL AND INTEGRAL CALCULUS

DERIVATIVES AND DIFFERENTIALS

Derivatives and Differentials. A **function** of a single variable x may be denoted by $f(x)$, $F(x)$, etc. The value of the function when x has the value x_0 is then denoted by $f(x_0)$, $F(x_0)$, etc. The **derivative** of a function $y = f(x)$ may be denoted by $f'(x)$, or by dy/dx. *The value of the derivative at a given point* $x = x_0$ is the **rate of change** of the function at that point; or, if the function is represented by a curve in the usual way (Fig. 1), the value of the derivative at any point shows **the slope of the curve** (that is, the slope of the tangent to the curve) at that point (positive if the tangent points upward, and negative if it points downward, moving to the right).

The **increment** Δy (read: "delta y"), in y is the change produced in y by increasing x from x_0 to $x_0 + \Delta x$; that is, $\Delta y = f(x_0 + \Delta x) - f(x_0)$. The **differential**, dy, of y is the value which Δy would have if the curve coincided with its tangent. (The differential, dx, of x is the same as Δx when x is the independent variable.) Note that the derivative depends only on the value of x_0, while Δy and dy depend not only on x_0 but also on the value of Δx. The ratio $\Delta y/\Delta x$ represents the slope of the secant, and dy/dx the slope of the tangent (see Fig. 1). If Δx is made to approach zero, the secant approaches the tangent as a limiting position, so that the derivative $= f'(x) =$

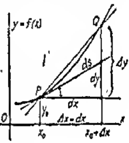

FIG. 1.

$$\frac{dy}{dx} = \lim_{\Delta x \doteq 0}\left[\frac{\Delta y}{\Delta x}\right] = \lim_{\Delta x \doteq 0}\left[\frac{f(x_0 + \Delta x) - f(x_0)}{\Delta x}\right].\quad \text{Also, } dy = f'(x)\,dx.$$

The symbol "lim" in connection with $\Delta x \doteq 0$ means "the limit, as Δx approaches 0, of ..." [A constant c is said to be the limit of a variable u if, whenever any quantity m has been assigned, there is a stage in the variation-process beyond which $|c - u|$ is always less than m; or, briefly, c is the limit of u if the difference between c and u can be made to become and remain as small as we please.]

To find the derivative of a given function at a given point: (1) If the function is given only by a curve, measure graphically the slope of the tangent at the point in question; (2) if the function is given by a mathematical expression, use the following rules for differentiation. These rules give, directly, the differential, dy, in terms of dx; to find the derivative, dy/dx, divide through by dx.

Rules for Differentiation. (Here $u, v, w, \ldots$ represent any functions of a variable x, or may themselves be independent variables. a is a constant which does not change in value in the same discussion; $e = 2.71828$.)

1. $d(a + u) = du.$ 2. $d(au) = a\,du.$
3. $d(u + v + w + \ldots) = du + dv + dw + \ldots$
4. $d(uv) = u\,dv + v\,du.$
5. $d(uvw\ldots) = (uvw\ldots)\left(\frac{du}{u} + \frac{dv}{v} + \frac{dw}{w} + \ldots\right).$
6. $d\frac{u}{v} = \frac{v\,du - u\,dv}{v^2}.$
7. $d(u^m) = mu^{m-1}du.$

Thus, $d(u^2) = 2u\,du$; $d(u^3) = 3u^2 du$; etc.

8. $d\sqrt{u} = \dfrac{du}{2\sqrt{u}}$. 9. $d\left(\dfrac{1}{u}\right) = -\dfrac{du}{u^2}$.

10. $d(e^u) = e^u du$. 11. $d(a^u) = (\log_e a)a^u du$.

12. $d \log_e u = \dfrac{du}{u}$. 13. $d \log_{10} u = (\log_{10} e)\dfrac{du}{u} = (0.4343\ldots)\dfrac{du}{u}$.

14. $d \sin u = \cos u\,du$. 15. $d \csc u = -\cot u \csc u\,du$.

16. $d \cos u = -\sin u\,du$. 17. $d \sec u = \tan u \sec u\,du$.

18. $d \tan u = \sec^2 u\,du$. 19. $d \cot u = -\csc^2 u\,du$.

20. $d \sin^{-1} u = \dfrac{du}{\sqrt{1-u^2}}$. 21. $d \csc^{-1} u = -\dfrac{du}{u\sqrt{u^2-1}}$.

22. $d \cos^{-1} u = -\dfrac{du}{\sqrt{1-u^2}}$. 23. $d \sec^{-1} u = \dfrac{du}{u\sqrt{u^2-1}}$.

24. $d \tan^{-1} u = \dfrac{du}{1+u^2}$. 25. $d \cot^{-1} u = -\dfrac{du}{1+u^2}$.

26. $d \log_e \sin u = \cot u\,du$. 27. $d \log_e \tan u = \dfrac{2du}{\sin 2u}$.

28. $d \log_e \cos u = -\tan u\,du$. 29. $d \log_e \cot u = -\dfrac{2du}{\sin 2u}$.

30. $d \sinh u = \cosh u\,du$. 31. $d \operatorname{csch} u = -\operatorname{csch} u \coth u\,du$.

32. $d \cosh u = \sinh u\,du$. 33. $d \operatorname{sech} u = -\operatorname{sech} u \tanh u\,du$.

34. $d \tanh u = \operatorname{sech}^2 u\,du$. 35. $d \coth u = -\operatorname{csch}^2 u\,du$.

36. $d \sinh^{-1} u = \dfrac{du}{\sqrt{u^2+1}}$. 37. $d \operatorname{csch}^{-1} u = -\dfrac{du}{u\sqrt{u^2+1}}$.

38. $d \cosh^{-1} u = \dfrac{du}{\sqrt{u^2-1}}$. 39. $d \operatorname{sech}^{-1} u = -\dfrac{du}{u\sqrt{1-u^2}}$.

40. $d \tanh^{-1} u = \dfrac{du}{1-u^2}$. 41. $d \coth^{-1} u = \dfrac{du}{1-u^2}$.

42. $d(u^v) = (u^{v-1})(u \log_e u\,dv + v\,du)$.

Derivatives of Higher Orders. The derivative of the derivative is called the second derivative; the derivative of this, the third derivative; and so on. *Notation:* if $y = f(x)$,

$$f'(x) = D_x y = \frac{dy}{dx};\quad f''(x) = D_x^2 y = \frac{d^2y}{dx^2};\quad f'''(x) = D_x^3 y = \frac{d^3y}{dx^3};\quad \text{etc.}$$

NOTE. If the notation d^2y/dx^2 is used, this must not be treated as a fraction, like dy/dx but as an inseparable symbol, made up of a symbol of operation, d^2/dx^2, and an operand y.

The geometric meaning of the second derivative is this: if the original function $y = f(x)$ is represented by a curve in the usual way, then at any point where $f''(x)$ is *positive*, the curve is *concave upward*, and at any point where $f''(x)$ is *negative*, the curve is *concave downward* (Fig. 2). When $f''(x) = 0$, the curve usually has a point of inflection.

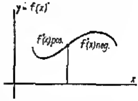

FIG. 2.

Differentials of Higher Orders. The differential of the differential is called the second differential; the differential of

in its action by the addition of tripping coils. Oil break switches are used in high-voltage work where the oil is necessary to extinguish the arc.

Circuit Breakers. Any of the foregoing switches equipped with a tripping device constitutes a circuit breaker. The tripping device is usually actuated by a solenoid which may be energized in various ways. In overload circuit breakers a solenoid coil connected in the main circuit trips the breaker when the current exceeds a certain value. If the coil is either connected in series with or across the circuit and is designed to trip the breaker when the current or voltage decreases beyond a certain value, the arrangements are, respectively, known as underload and undervoltage circuit breakers. By means of a combination shunt and series coils the circuit breaker may be made to trip when the energy reverses. Circuit breakers may trip when the difficulty is immediately cleared by a local breaker or fuse. In order that service shall not be interrupted unnecessarily, automatically reclosing breakers are used. After tripping, an automatic mechanism operates to reclose the breaker. If the short-circuit still exists, the breaker cannot reclose. The breaker thus attempts to reclose two or three times and then if the short-circuit still exists it remains permanently locked out.

In the rate-of-current-rise breakers the tripping circuit is nearly noninductive and is in parallel with a highly inductive branch. The more nearly a fault approaches a dead short-circuit, the greater the rate of current rise and the greater the proportion of current forced into the tripping circuit. Hence it follows that the greater the rate at which the current rises, the lower the value of total current at which the breaker trips. If motors or other loads seldom exceed their maximum ratings, fuses may be used for protection because of their low first cost. To avoid delays incurred by looking for and replacing fuses, the tendency at the present time is to use circuit breakers and thus reduce the time of shutdown to a minimum.

Power Distribution

Distribution Systems. The choice of the system of power distribution is determined by the type of power that is available and by the nature of the load. To transmit a given power over a given distance with a given power loss (I^2R), the weight of conductor varies inversely as the square of the voltage. Incandescent lamps will not operate economically at voltages much higher than 120 volts; the most suitable voltages for d-c motors are 230 and 550 volts, although 550 volts is practically obsolete, except for railway motors; for a-c motors, standard voltages are 220, 440, and 550 volts, three-phase.

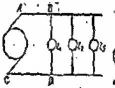

FIG. 76.—Parallel circuit.

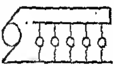

FIG. 77.—Loop circuit.

Parallel Circuits. Power is usually distributed at constant potential, and all the devices or receivers in the circuit are connected in parallel, giving a constant-potential system (Fig. 76). If conductors of constant cross section are used and all the lamps, L_1, L_2, etc., are operating, there will be a greater voltage IR drop in the portion of the circuit AB and CD than in the other portions; also the voltage will not be the same for the different lamps but will decrease along the mains with distance from the generating end.

Loop Circuits. A more nearly equal voltage for each load is obtained in the loop system (Fig. 77). The electrical distance from one generator

appliances. Pure nickel is used to satisfy the high requirements in the fabrication of radio tubes, such as the elimination of all gases and impurities in the metal parts. It has also other uses such as in incandescent lamps, for combustion boats, laboratory accessories, and resistance thermometers.

Carbon withstands high temperatures and has high resistance; its temperature coefficient is negative; it will safely carry about 125 amp per sq in. Amorphous carbon has a resistivity of 3,800 to 4,100 microhms per cc, retort carbon about 720 microhms, and graphite about 812 microhms per cc. The properties of any particular kind of carbon depend on the temperature at which it was fired. Carbon for rheostats may best be used in the form of compression rheostats.

MAGNETS

A **permanent magnet** is one that retains a considerable amount of magnetism indefinitely. Permanent magnets are used in electrical instruments, telephone receivers, radio loudspeakers, magnetos, and for any purpose where a constant magnetic field is desired. The steel used should have high retentivity, a high remanence, and a high coercive force (see Fig. 11, p. 1703). These properties are usually found with hardened steel and its alloys.

Five percent tungsten steel having small percentages of chromium and manganese and 0.63 to 1.0 percent carbon is frequently used. Special chromium-cobalt steels have been developed which give the following analysis in percent: "Alpha" quality—C, 0.56; Mn, trace; Si, 0.28; P, 0.016; S, 0.040; Cr, 3.31; Co, 30.18. Another successful alloy is C, 1.0; Cr, 3.50. An alloy, **Alnico**, consisting of aluminum, iron, nickel, and cobalt, developed by the General Electric Co., has permanent magnetic properties far superior to the foregoing alloys. The composition of Alnico II, which because of its high stability is commonly used with instruments and meters, is as follows: Al, 10; Ni, 17; Co, 12.5; Cu, 6.0.

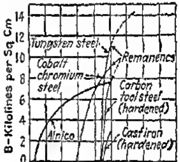

FIG. 86.—Characteristics of permanent-magnet materials.

Permanent magnets operate over the portion *DE* of the hysteresis loop (Fig. 11), and high remanence and high coercive force are both desirable. The area of *ODE* is proportional to the energy stored in the magnet and is a criterion of the material. In Fig. 86 are shown the characteristics of different magnet materials. It will be noted that although Alnico has less remanence than tungsten or cobalt-chromium steel the coercive force and area are very much larger.

The steels for permanent magnets are cut in strips, heated to a red-hot temperature and forged into shape, usually in a "bulldozer." If they are to be machined, they are cooled in mica dust to prevent air hardening. They are then ground, tumbled, and tempered. Permanent magnets are magnetized either by placing them over a bus bar carrying a very heavy direct current or by placing them across the poles of a powerful electromagnet.

Unless permanent magnets are subjected to artificial aging, they gradually deteriorate or weaken. With magnets for electrical instruments, where a constant field strength is imperative, artificial aging is accomplished by mechanical vibration or by immersion in oil at 250 F for a period of a few hours.

In an **electromagnet** the magnetic field is produced by an electric current. The core is usually made of soft iron or mild steel because, the permeability being higher, a stronger magnetic field may be obtained. Also since the retentivity is low, there is little trouble due to the sticking of armatures when

terminal to the other through any receiver is the same as that through any other receiver, and the voltage at the receivers may be maintained more nearly equal, but at the expense of additional conductor material.

Series-parallel Circuit. For incandescent lamps the power must be at low voltage (115 volts) and the voltage variations must be small. If the transmission distance is considerable or the loads are large, a large or perhaps prohibitive investment in conductor material would be necessary. In some special cases, lamps may be operated in groups of two in series as shown in Fig. 78. The transmitting voltage is thus doubled, and, for a given number of lamps, the current is halved, the permissible voltage drop (IR) in conductors doubled, the conductor resistance quadrupled, the weight of conductor material thus being reduced to 25 percent of that necessary for simple parallel operation.

Three-wire System. In the series-parallel system the loads must be used in pairs. To overcome this objection and at the same time to obtain the economy in conductor material of operating at higher voltage, the three-

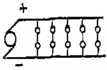

FIG. 78.—Series-parallel system.

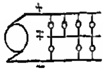

FIG. 79.—Three-wire system.

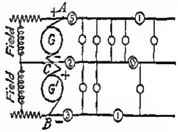

FIG. 80.—Three-wire system with two generators.

wire system is used. It consists merely of adding a third wire or neutral to the system of Fig. 78 as shown in Fig. 79.

If the neutral wire is of the same cross section as the two outer wires, this system requires only 37.5 percent of the copper required by an equivalent two-wire system. Since the neutral ordinarily carries less current than the outers, it is usually smaller and the ratio of copper to that of the two-wire system is even less than 37.5 percent (see Table 23).

When there is an equal number of lamps on each half of the system, there will be no current flowing in the middle or neutral wire, and the condition is the same as that shown in Fig. 78. When the number of lamps on the two sides is different, the neutral wire will carry a current equal to the difference of the currents in the outside wires. For example, if each of the lamps in the system shown in Fig. 80 takes 1 amp, the currents in each part of the system will be given by the numbers on the ammeters shown connected in the system.

The three-wire system shown in Fig. 79 is not practicable because no means are provided for holding the neutral at its correct potential. If, for example, four lamps are in operation on one side of the system and three on the other, as shown, the voltages on the two sides of the system become seriously unbalanced and the three lamps are subjected to overvoltage. One method of supplying the neutral is shown in Fig. 80 where each side of the system is supplied by a separate generator. This is open to the objection of the greater complications of two machines, greater cost, more floor space, and the lesser efficiency of two machines.

the circuit is opened. Electromagnets may have the form of simple solenoids, ironclad solenoids, plunger electromagnets, and electromagnets with external armatures.

A solenoid is a winding of insulated conductor and is wound helically; the direction of winding may be either right or left. A portative electro-

magnet is one designed only for holding material brought in contact with it. **A tractive electromagnet** is one designed to exert a force on the load through some distance and thus do work. The **range** of an electromagnet is the distance through which the plunger will perform work when the winding is energized. After the core becomes saturated, the pull varies almost directly with the number of ampere-turns. For long range of operation, the plunger type of tractive magnet is best suited, for the length of core is governed practically by the range of action desired, and the area of the core is determined by the pull. **Solenoid and plunger** is a solenoid provided with a movable iron rod or bar called a plunger. When the coil is energized, the iron rod becomes magnetized and the mutual action of the field in the solenoid on the poles created on the plunger causes the plunger to move within the solenoid. This force becomes zero only when the magnetic centers *of the plunger and solenoid coincide.* If the load is attached to the plunger, work will be done until the force to be overcome is equal to the force that the solenoid exerts on the plunger. When the iron of the plunger is not saturated, the strength of magnetic field in the solenoid and the induced poles are both proportional to the exciting current, so that the pull varies as the *current squared.* When the plunger becomes highly saturated, the pull varies almost *directly* with the current.

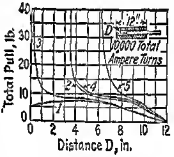

FIG. 87.—Pull of solenoid on plunger.

1. Coil and plunger; 2, coil and plunger with stop; 3, ironclad coil and plunger; 4 and 5, same as 3 with different lengths of stop.

The **maximum uniform pull** occurs when the end of the plunger is at the center of the solenoid and is equal to

$$F = CAnI/l \qquad (118)$$

Balancer Set. Another method of obtaining the neutral is to use a balancer set. This consists of two similar shunt or compound machines coupled together with the armatures connected in series across the outer lines as shown in Fig. 81. When the loads are balanced, there is no neutral current and the two machines merely run idle as motors, being connected in series across the line. If the load on one side of the system becomes greater than that on the other side, the machine on the more heavily loaded side operates as a generator and pumps some of the neutral current to its side of the line. The remainder of the neutral current goes through the other machine supplying it with the power that enables it to operate as a motor and and drive the generator. For example, in Fig. 81, the load on the positive side of the system is greater than that on the negative side. Hence, the machine G on the positive side is operating as a generator and the machine M is operating as a motor. If the machines are compounded so that when operating as a generator the winding is cumulative and hence is differential when a motor, the voltage unbalance with change in load can be made practically zero.

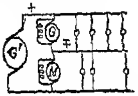

Fig. 81.—Motor-generator balancer.

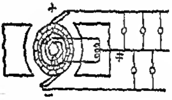

Fig. 82.—Three-wire generator.

Since balancer sets take power continuously, they are used for the most part on large systems of high diversity where the percentage unbalance is small.

Three-wire Generator. The three-wire generator is another common method of obtaining a neutral. It is a regular generator that would ordinarily be used to supply the outer wires with power. Two or more taps a and b are, however, brought out from the armature winding to two slip rings (Fig. 82). A compensator or reactance coil of low resistance is connected across the slip rings. The neutral of the three-wire system is connected to its center point. The voltage across the slip rings is alternating. Because of its choking action, but little alternating current flows in the compensator. Direct current flows back through the compensator to the armature. The inductance of the compensator has no effect on the steady direct current, and the resistance of the compensator is low so that there is little voltage drop due to the direct current. Two or more compensators with their neutrals connected may be used. With two such compensators, the second compensator is connected to slip rings that are tapped to the armature winding at points 90 electrical degrees from the first. In order to eliminate all but one slip ring, the reactance coil is sometimes mounted within the spider of the armature.

Wiring Calculations

Wiring Calculations for Direct-current Circuits. The determination of the proper size of conductor is influenced by a number of factors. Except for short distances, the minimum size of conductor recommended by the National Board of Fire Underwriters in Table 20, which is based on the maximum permissible current for each type of insulation, cannot be used;

where A is the cross-sectional area of the plunger, sq in.; n the number of turns; I the current, amp; l the length of the solenoid, in.; and C the pull, lb per sq in. per amp turn per in.. C depends on the proportions of the coil, the degree of saturation, the length, and the physical and chemical purity of the plunger. Table 25 gives values of C for several different solenoids.

Curve 1, Fig. 87, shows the characteristic pull of an open-magnetic circuit solenoid, 12 in. long, having 10,000 amp-turns or 833 amp-turns per in.

When a strong pull is desired at the end of the stroke, a stop may be used as shown in Fig. 88. Curve 2, Fig. 87, shows the pull obtained by adding a stop to the plunger. It will be noted that, except when the end of the plunger is near the stop, the stop adds little to the solenoid pull. The pull is made up of two components—one due to the attraction between plunger and winding and the other one due to the attraction between plunger and stop. The equation for the pull is

$$P = AIn[(In/l_a^2C_1^2) + (C/l)] \text{ lb} \tag{119}$$

where A is the area of the core, sq in.; n is the number of turns; l_a is the length of gap between core and stop; and C and C_1 are constants. At the beginning of the stroke the second member of the equation is predominant, and at the end of the stroke the first member represents practically the entire pull. Approximate values of C and C_1 are $C_1 = 2{,}660$ (for l greater than $10d$), $C = 0.0096$, where d is the diameter of the plunger, in.

FIG. 88.—Solenoid with stop.

FIG. 89.—Conical plunger and stop.

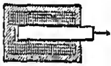

FIG. 90.—Ironclad solenoid.

The range of uniform pull may be extended by the use of conical ends of stop and plunger, as shown in Fig. 89. A stronger magnet mechanically may be obtained by using an ironclad solenoid (Fig. 90), in which an iron return path is provided for the flux. Except for low flux densities and short air gaps the dimensions of the iron return path are of no practical importance, and the fact that an iron return path is used does not affect the pull curve except at short air-gaps. This is illustrated in Fig. 87 where curves 3, 4, and 5 are typical pull curves for this same solenoid when it is made ironclad, each curve corresponding to a different position of the stop.

Mechanical jar at the end of the stroke may be prevented by leaving the end of the solenoid open. The plunger then comes to equilibrium when its middle is at the middle of the winding, thus providing a magnetic cushion effect. Electromagnets with external armatures are best adapted for short-range work, and the best type is the horseshoe magnet. The pull for short-range mangets is expressed by the equation

$$F = B^2A/72{,}134{,}000 \text{ lb} \tag{120}$$

where B is the flux density in lines per sq in. and A the area of the core in sq in. A greater holding power is obtained if the surfaces of the armature and core are not machined to an absolutely smooth contact surface. If the surface is slightly irregular, the area of contact A is reduced but the flux density B is increased approximately in proportion (if the iron is being oper-

the size of conductor must be larger in order that the voltage drop (IR) shall not be too great. With branch circuits supplying an incandescent-lamp load, this drop should not be more than a small percentage of the voltage between wires. Good practice in interior wiring allows a drop of not more than 3 volts in feeder circuits from the main switchboard to the farthest tablet board and a drop of not more than 1 volt from any tablet board to the farthest lamp.

The resistance of 1 cir mil-ft of commercial copper may be taken as 10.8 ohms. The resistance of a copper conductor may be expressed as $R = 10.8l/A$, where l is the length in feet and A the area in circular mils. If the length is expressed in terms of the transmission distance d (since the two wires are usually run parallel), the voltage drop IR to the end of the circuit is

$$e = 21.6Id/A \tag{112}$$

and the size of conductor in circular mils necessary to give the permissible voltage drop e is

$$A = 21.6Id/e \tag{113}$$

If e is expressed as a percentage x of the voltage E between conductors, then

$$A = 2{,}160Id/xE \tag{114}$$

Example. Find the size of conductor to supply power to a 10-hp 220-volt d-c motor 500 ft from the switchboard with 5 volts drop. Assume a motor efficiency of 86 percent. The motor will then require a current of $(10 \times 746)/(0.86 \times 220) = 39.4$ amp. From Eq. (113), $A = 21.6 \times 39.4 \times 500/5 = 85{,}100$ cir mils. The nearest standard wire is No. 1 (A. W. G.). See Table 19.

The calculation of the size conductor for d-c three-wire circuits is made in practically the same manner. With a balanced circuit no current flows in the neutral wire and the current in each outside wire will be equal to one-half the sum of the currents taken by all the receiving devices connected between neutral and outside wires plus the sum of the currents taken by the receivers connected between the outside wires. Using this total current and neglecting the neutral wire, make calculations for the size of the outside wires by means of Eq. (113). The neutral wire should have the same cross section as the outside wires in interior wiring.

FIG. 83.—Three-wire 220–110-volt main.

Example. What size wire should be used for the three-wire main of Fig. 83? Allowable drop is 3 volts and the distance to the load center 40 ft; circuit loaded with two groups of receivers each taking 60 amp connected between the neutral and the outside wires, and one group of receivers taking 20 amp connected across the outside wires. Solution: Load $= (60 + 60)/2 + 20 = 80$ amp. Substituting in Eq. (113), cir mils $= 21.6Id/e = 21.6 \times 80 \times 40/3 = 23{,}030$ cir mils.

Referring to Table 20, No. 6 wire, which has an area of 26,250 cir mils, is the next size larger. This size of wire would satisfy the voltage-drop requirements, but rubber-insulated No. 6 has a safe carrying capacity of but 50 amp. The current in the circuit is 80 amp. Therefore, with rubber-insulated wire, No. 2, which has a carrying capacity of 90 amp, should be used. The neutral wire should be the same size as the outside wires. For exposed wiring with slow-burning or weatherproof insulation, No. 4 wire, which has a capacity of 90 amp, could be used.

Wiring calculations for a-c circuits are essentially the same as for d-c circuits, but other factors such as power factor, reactance, and skin effect may require consideration. Skin effect becomes pronounced only when very large

ated below saturation), and the pull is increased since it varies as the square of the density B. Non-magnetic stops should be used if it is desired that the armature may be released readily when the current is interrupted.

Lifting magnets are of the portative type in that their function is merely to hold the load. The actual lifting is performed by the hoisting apparatus. The magnet is almost toroidal in shape. The coil shield is of manganese steel which is very hard and thus resists wear and is practically nonmagnetic. The holding power

$$F = B^2A/72{,}134{,}000 \text{ lb} \tag{121}$$

where B is in lines per sq in. and A the area of the holding surface in sq in. It is difficult to calculate accurately the holding force of a lifting magnet for it depends on the magnetic characteristics of the load, the area of contact, and the manner in which the load is applied.

Rapid action in a magnet may be obtained by reducing the time constant (see p. 1708) of the winding and by subdividing the metal parts to reduce induced currents which have a demagnetizing effect when the circuit is closed. The movement of the plunger through the winding causes the winding and its bobbin to cut a magnetic field; if the bobbin is of metal and not slotted longitudinally, it is a short-circuited turn linked by a changing magnetic field and hence currents are induced in it. These currents oppose the flux and hence reduce the pull during the transient period. They also cause some heating. Where it is found impossible to reduce the time constant sufficiently, an electromagnet designed for a voltage much lower than normal is often used. In many electromagnets, the plunger, at the completion of its stroke, automatically connects in series with its winding a resistance of sufficient magnitude to reduce the current to a safe value. The solenoids on many automatic motor-starting panels are designed in this manner, as the extremely short time of overload produces very rapid action but does not injure the winding. When **slow action** is desired, it can be obtained by using solid cores and yoke and by using a heavy metallic spool or bobbin for the winding. A separate winding short-circuited on itself is also used to some extent.

Sparking at switch terminals may be reduced or eliminated by neutralizing the inductance of the winding. This neutralization is accomplished by winding a separate short-circuited coil with its wires parallel to those of the active winding. (This method can be used with d-c magnets only.) This is not economical, since one-half of the winding space is wasted. By connecting a capacitor across the switch terminals, the energy of the inductive discharge on opening the circuit may be absorbed. For the purpose of neutralizing the inductive discharge and causing a quick release, a small **reverse current** may be sent through the coil winding automatically upon opening the circuit. Tinfoil sleeves placed over the various layers of the winding absorb energy when the circuit is broken and reduce the energy dissipated at the switch terminals. This scheme can be used for d-c magnets only. **Sticking** of the parts of the magnetic circuit due to residual magnetism may be prevented by the use of non-magnetic stops. In the case of lifting magnets subjected to rough usage and hard blows (as in a steel works), these stops usually consist of plates of manganese steel, which are extremely hard and non-magnetic.

Alternating-current Tractive Magnets. Because of the iron losses due to eddy currents, the magnetic circuits of a-c electromagnets should be composed of laminated iron or steel. The magnetic circuit of large

conductors are used for alternating current. For interior wiring, conductors larger than 700,000 cir mils should not be used, and many prefer not to use conductors larger than 300,000 cir mils. Should the required copper cross section exceeds these values, a number may be operated in parallel.

For voltages under 5,000 the effect of line capacitance may be neglected. With ordinary single-phase interior wiring, where the effect of line reactance may be neglected and where the power factor of the load (incandescent lamps) is nearly 100 percent, the calculations are made the same as for d-c circuits. Three-wire a-c circuits of ordinary length with incandescent lamp loads are also determined in the same manner. When the load is other than incandescent lamps, it is necessary to know the power factor of the load in order

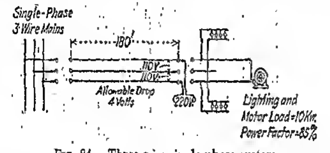

FIG. 84.—Three-wire single-phase system.

to make calculations. When the exact power factor cannot be accurately determined, the following approximate values may be used: incandescent lamps, 0.95 to 1.00; lamps and motors, 0.75 to 0.85; motors, 0.5 to 0.80. Equation (115) gives the value of current in a single-phase circuit.

$$I = \frac{P \times 1{,}000}{E \times p} \tag{115}$$

where I is the current, amp; P the kilowatts; E the load voltage; and p the power factor of the load. The size of conductor is then determined by substituting this value of I in Eq. (113) or (114).

Example. In Fig. 84, load = 10 kw; voltage of circuit = 220-110, three-wire; power factor = 0.85; distance = 180 ft; allowable drop = 4 volts. Substituting these values in (115), the current $I = (10 \times 1{,}000)/(220 \times 0.850) = 53.5$ amp. Substituting again in (113), cir mils = $21.6 \times 53.5 \times 180/4 = 52{,}000$. The next larger standard size of wire is No. 3 (52,630 cir mils), which will carry 80 amp (see Table 20).

For three-phase three-wire a-c circuits the current per wire

$$I = 1000P/\sqrt{3}\,Ep = 580P/Ep \tag{116}$$

Computations are usually made of voltage drop *per wire*. Hence, if reactance can be neglected, the conductor cross section in cir mils is one-half that given by Eq. (113). That is,

$$A = 10.8Id/e \text{ cir mils} \tag{117}$$

where e in (117) is the voltage drop per wire. The voltage drop between any two wires is $\sqrt{3}\,e$.

Example. In Fig. 85, load = 10 kw; voltage of circuit = 220; power factor = 0.85; distance = 360 ft; allowable drop per wire = 4 volts. Substituting in (116), $I = (580 \times 10)/(220 \times 0.85) = 31$ amp. Substituting in (117), $A = 10.8 \times 31 \times 360/4 = 30{,}100$ cir mils.

The next larger standard size wire No. 5 (33,100 cir mils) will carry with rubber insulation 55 amp and with other insulations 80 amp (Table 20) and is therefore ample in section for 31 amp. Three No. 5 wires would be used for this circuit.

For other frequencies the reactance will be in direct proportion to the frequency.

Where all the wires of a circuit, two wires for a single-phase, four wires for a two-phase, and three wires for a three-phase circuit, are carried in the same conduit or where the wires are separated less than 1 in. between centers, the effect of line (inductive) reactance may ordinarily be neglected. Where circuit conductors are large and widely separated from one another and the circuits are long, the inductive reactance may increase the voltage drop by a considerable amount over that due to resistance alone. Such problems are treated the same as high-voltage problems. Line reactance decreases somewhat as the size of wire increases and decreases as the distance between wires decreases.

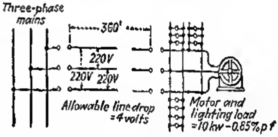

Fig. 85.—Three-phase lamp and induction-motor load.

Wires

Insulated Wires. The following types of insulated wire are in common use for low-voltage wiring: rubber covered; synthetic (SN); weatherproof (WP); slow burning (SB);

magnets is usually built up of thin sheets of sheet metal held together by means of suitable clamps. Small cores of circular cross section usually consist of a bundle of soft iron wires. Since the iron losses increase with the flux density, it is not advisable to operate at as high a density as with direct current. The current instead of being limited by the resistance of the winding *is now determined almost entirely by the inductive reactance as the resistance* is small. With the removal of the load the current rises to high values. The pull of a-c magnets is nearly constant irrespective of the length of air gap.

In a **single-phase magnet** the pull varies from zero to a maximum and back to zero twice every cycle, which may cause considerable chattering of the armature against the stop. This may be prevented by the use of a spring or, in the case of a solenoid coil, by allowing the plunger to seek its position of equilibrium in the coil. **Chattering** may also be prevented by the use of a short-circuited winding or shading coil around one tip of the pole piece or by the use of polyphase. In a **two-phase magnet** the pull is constant and equal to the maximum instantaneous pull produced by one phase so long as the voltage is a sine function. In a **three-phase magnet** under the same conditions the pull is constant and equal to 1.5 times the maximum instantaneous pull of one phase. *Should the load become greater than the minimum instantaneous pull*, there will be chattering as in a single-phase magnet.

Heating of Magnets. The lifting capacity of an electromagnet is limited by the permissible current-carrying capacity of the winding, *which in turn is dependent on the amount* of heat energy that the winding can dissipate per unit time without exceeding a given temperature rise. Coils wound with wire having cotton insulation will, in general, be operating at a safe temperature if the average power expended does not exceed 0.5 watt per sq in. of radiating surface.

Winding space factor
FIG. 91. FIG. 92.

Design of Exciting Coil. Let n be the number of turns, l the mean length of turn in in. ($l = 2\pi r$, where r is the mean radius, in.), A the cross section of wire in cir mils. The resistance of a cir mil-ft of copper is practically 12 ohms at 60 C, or 1 ohm per cir mil-in. Hence the resistance, $R = nl/A$ ohms; the current, $I = EA/nl$; the amp turns, $nI = EA/l$; the power to be dissipated, $P = E^2A/nl$. From the foregoing equations the cross section of wire and the number of turns may be calculated.

Space Factor of Winding. The "space factor" is the ratio of the net volume of conductor in a given winding to the gross volume of the winding. Only in the theoretical case of uninsulated square or rectangular conductor may the space factor be 100 percent. For wire of circular section with insulation of negligible thickness, wound as shown in Fig. 91, the space factor will be 78.5 percent. When the turns of wire are "bedded," as shown in Fig. 92 (which is the case in most windings, particularly with smaller-sized wires), *there is a theoretical gain of about 7 percent* in space factor (Underhill, *Elec. World*, 53, 155, 1909). Experiments have shown that in most cases this gain is about neutralized in practice by the flattening out of the insulation of the wire due to the tension used in winding. When wound in a haphazard manner, the space factors of magnet wires vary according to size, substantially as follows:

	Double cotton covered					Single cotton covered		
Size, A. W. G.	0	5	10	15	20	25	30	35
Space factor, percent	60	53.8	45.5	35.1	32.2	32	25.7	16

and for wiring fixtures, rubber covered and heat resisting. Varnished cloth (V) and slow-burning weatherproof (SBW) are little used at the present time. **Rubber-covered wire** for voltages up to 600 volts has an unbroken rubber wall protected with cotton braid impregnated with moistureproof compound. Type letter (R) is a code grade rubber with a maximum operating temperature 122 F, (RP) a better grade or performance grade rubber 140 F, (RH) a heat-resistant rubber 167 F, (RW) a moisture-resistant rubber for wet locations 122 F, (RHT) a small diameter heat-resistant rubber 167 F for general building wiring, (RPT) a small diameter performance rubber 140 F

For aluminum wire the allowable carrying capacity shall be taken as 84 percent of those given in the table for the respective sizes of copper wire with the same kind of covering.

[1] For 4 to 6 conductors the current is 80 per cent.
For 7 to 9 conductors the current is 70 per cent.

in sizes 14–10 for rewiring existing raceways for increased loads, (RU) a very thin high quality rubber 140 F in sizes 14–10 for rewiring existing raceways for increased loads. *Synthetic* (SN) is a *solid synthetic* compound of small diameter 140 F in sizes 14 to 4/0 for rewiring existing raceways for increased loads. **Slow-burning wire** has three braids of cotton, impregnated with a fire-resisting compound; its use is limited to temperatures over 185 F. **Weatherproof wire** is cheaper than other wires since the insulation consists merely of three braids of cotton impregnated with moistureproof compound. This wire is limited to outdoor use and must be supported on insulators as if the wire were bare, for the covering has no effective insulating properties. **Fixture wire** is made with either heat-resistant or rubber insulation. The rubber-covered wire is used for out-door fixtures and in fixtures where it is not subjected to extreme heat, as well as where the voltage between wires may be between 300 and 600 volts. The heat-resistant wire must be used in fixtures where the temperature exceeds 120 F. Fixtures should be wired with asbestos-covered heat-resistant fixture wire except that

Magnet wire is a soft insulated copper wire of high conductivity. It may be obtained in square, rectangular, and circular section, but the round or cylindrical wire is used almost entirely in the smaller sizes. Ribbons are frequently used in the larger sizes. Cotton covering is used on large and medium-sized wires but silk is used for the very small wires. Both cotton and silk insulation char at about 260 F and so are unsuitable for high-temperature operation. **Enameled magnet** wire is used where it is necessary to have the thinnest insulation possible and still retain high insulation resistance. Enamel covering is now highly resistant to abrasion and is used even on the larger sizes of wire. Enamel insulation will withstand a temperature of 400 F for long periods of time without deterioration. **Enamel and cotton** are now much used instead of the double textile coverings. The advantage lies in the greater space factor and increased dielectric strength. The cotton has no dielectric strength but acts as a spacer. With enamel it acts as a cushion to protect the enamel and as an absorbent when the winding is impregnated. The enamel has substantial dielectric strength.

Magnet wire provided with asbestos covering is used on magnets and spools operating at high temperature. Wire insulated in this manner may be operated at near red heat without injuring the insulation. **Fiberglas**, a thread spun from very fine glass fibers, is now being used extensively as high temperature insulation for wires. Its mechanical properties are far superior to those of asbestos, and it can withstand temperatures approaching red heat. The thread can also be woven into a fabric and used for insulation, particularly in tape form. **Formex**, an enameled wire, has great adherence, stretchability, and mechanical toughness.

Electron Tubes and Radio

Electron tubes depend for their operation on the fact that a hot body emits extremely small negatively charged particles of electricity called electrons. An **electron tube** with two electrodes is called a **diode** and consists of a hot filament (Fig. 93) and a plate P in a highly evacuated glass tube.

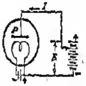

FIG. 93.—Two-electrode tube.

When an emf E is applied between the plate and the filament so that the plate is positive and the filament is negative, the electrons emitted by the filament are drawn to the plate. The current, however, flows from plate to filament since the conventional direction of current flow is opposite to the direction of flow of the electrons which are negative charges. The relation of the current to the voltage, for three different temperatures of the filament, is given in Fig. 94. At any given filament temperature T_1 the current increases rapidly at first with increase in voltage and then at some point such as *a* the current becomes essentially constant. This is **filament saturation** and occurs when the voltage is sufficiently high to draw all the electrons emitted by the filament at the given temperature. When the temperature of the filament is increased to temperatures T_2 and T_3, more electrons are emitted by the filament and saturation occurs at higher values of voltage. When the filament is positive and the plate negative, the electrons are all drawn to the filament and no current flows. Hence this tube has **unidirectional conduction** and may be used as a rectifier. It is the basis of

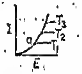

FIG. 94.—Current-voltage characteristics of two-electrode tube.

the **kenotron** and **tungar rectifier** (p. 1753). It is also used as the detector in receiving sets (pp. 1778, 1780).

In the **three-electrode tube** or **triode** (Fig. 95) a grid is placed between filament and plate but very close the filament. A relatively small difference of potential applied between grid and filament has a much greater effect on the electron flow to the plate than when applied between filament and plate. A very small amount of energy applied to the grid can, therefore, control a very much greater amount of energy going to the plate. The energy applied to the grid may be zero as grid potential need not be accompanied by current. This characteristic of the tube makes it a very efficient amplifier and modulator of electric waves. It may also be used as a rectifier and detector. Figure 96 shows typical static relations between grid voltage and plate current in a triode with different plate voltages. The plate current I_p is plotted as a function of grid voltage for three different values of plate voltage E_1, E_2, E_3. In order to make the plate current zero, a negative

FIG. 95.—Three-electrode tube.

FIG. 96.—Static characteristics of three-electrode tube. (See Fig. 104.)

potential such as $-E_2'$ must be applied to the grid. If a small a-c voltage e_g *(Fig. 96) (see Fig. 99)* is applied to the grid, a corresponding variation of plate current i_p results. If the tube is made to operate on the straight portion of the characteristic by applying a negative polarizing voltage $-E_g$ to the grid by means of a C battery (see Fig. 95), the i_p wave is similar to the e_g wave and there is no distortion. When the grid is negative, the grid current I_g must be zero. Tubes are usually operated with a negative grid bias since it reduces distortion. They may, however, be made to operate on any desired portion of the characteristic by means of the C battery.

The plate current i_p (Fig. 96) represents a considerable increase of power over the grid input and may be utilized for operating a loudspeaker or the power may be further amplified.

In order to reduce the hum that occurs when a-c supply is used, the cathode frequently consists of a metallic cylinder with a heater inside. The heater usually is a hairpin loop of tungsten wire enclosed within the cylinder and insulated from it by refractory material (see Figs. 97 and 98 in which E_a may be replaced by a-c voltage). Obviously, the cyclic variation in the temperature of the cylinder and, therefore, in the emission is much less than for the filament alone.

Table 23. For Selecting Wire and Fuse Sizes for Motor Branch Circuits.

[a] For the running protection of 1 hp and less, the protection given in columns 7, 8, and 9 may be considered sufficient, but if the motor is located out of sight of the operator, the values in columns 5 and 6 should be used.

[b] Single-phase repulsion or split phase.

[c] High-reactance squirrel-cage motors, designed to limit the starting current by means of deep-slot secondaries or double-wound secondaries.

[d] Code letters marked on motor name-plates indicate a ratio of current taken with the rotor locked, to rated current. Letter A indicates 0 to 3.14; B to E, 3.15 to 4.99; F to R, 5.0 to 14.0 and higher. Adopted standard by N.E.M.A.

when the fixture wire will not be subjected to temperatures higher than 194 F, a cotton-covered heat-resistant fixture wire may be used. Table 20 gives the carrying capacity of insulated copper wire.

Resistor Materials

For use in rheostats, electric furnaces, ovens, heaters, and many electrical appliances, a resistor material with high melting point and high resistivity,

With radio-frequency amplification, the capacitance between the grid and plate is objectionable in that it causes feedback and limits the possible amplification of the tube. This capacitance is reduced to a very small value by the use of a screen-grid **tetrode** (Fig. 97). The screen grid completely surrounds the plate and is connected by a tap to the B battery so that its potential is negative with respect to the plate.

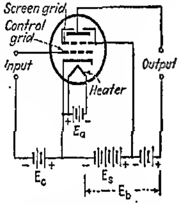

Fig. 97.—Screen-grid tetrode.

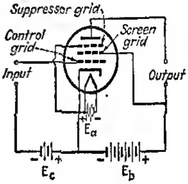

Fig. 98.—Pentode.

When the plate becomes negative with respect to the screen grid, secondary electrons emitted by the plate, owing to the impact of the primary electrons from the filament, are drawn to the screen grid. This reduces the plate current in the region of operation and curtails the power output of the tube. This effect may be eliminated by a **suppreseor** grid between the ecreen grid and the plate (Fig. 98). The suppressor grid is connected to the filament and hence is alwaye negative with respect to the plate. Therefore, any electrons emitted by the plate are driven back. Such a tube is a **pentode.**

Figure 99 ehows the connections of a tube for use as an **amplifier** with inductive coupling in which the emf e_g is amplied to e_g' (see Fig. 96). The plate current i_p flows through the primary N_1 of an amplifying transformer. Since the ratio of secondary to primary turns N_2/N_1 is something like 10:1, the secondary emf e_1' is much greater than that of the primary. For audio frequencies the amplifying transformer has a laminated iron core; with radio frequencies an air-core transformer is used. The amplified emf e_g' may be fed to a second amplifier. In this manner several stages of amplification are obtainable. Resistance and capacitive couplings are also used in amplifiers.

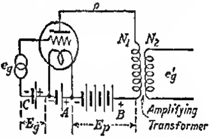

Fig. 99.—Vacuum tube as amplifier.

As the grid voltage e_g swings more negative (Fig. 96) distortion is produced in the amplified plate current i_p because of the curvature of the $I_p - E_g$ characteristic. In fact, with too great a negative swing of e_g a portion of the negative half of the i_p wave may become eliminated, and large distortion results. In order to reduce such distortion to a very small amount and increase the power output per tube, the **push-pull amplifier**, shown in Fig. 100, is used. There is a center tap o at the center of secondary ab of the input transformer to which the negative of the C battery is connected. The

which does not disintegrate or corrode at high temperatures, is necessary. These requirements are met by the nickel-chromium and nickel-chromium-iron alloys. For electrical instruments and measuring apparatus, the resistor material should have high resistivity, low temperature coefficient, and, for many uses, low thermoelectric power against copper. The properties of resistor materials are given in Table 24. Most of these materials are available in ribbon as well as in wire form. Cast-iron and steel wire are efficient and economical resistor materials for many uses, such as power-absorbing rheostats and motor starters and controllers.

Advance has a low temperature coefficient and is useful in many types of measuring instrument and precision equipment. Because of its high thermo-

electric power to copper, it is valuable for thermoelements and pyrometers. It is non-corrosive and is used to a large extent in industrial and radio rheostats. **Hytemco** is a nickel-iron alloy characterized by a high temperature coefficient and is used advantageously where self-regulation is required as in immersion heaters and heater pads. **Magno** is a manganese-nickel alloy which is used in the manufacture of incandescent lamps and radio tubes. **Manganin** is a copper-manganese-nickel alloy which, because of its very low temperature coefficient and its low thermal emf with respect to copper, is very valuable for high-precision electrical measuring apparatus. It is used for the resistance units in bridges, for shunts, multipliers, and similar measuring devices. **Nichrome V** is a nickel-chromium alloy free from iron, is noncorrosive, nonmagnetic, withstands high temperatures, and has high resistivity. It is recommended as material for heating elements in electric furnaces, hot-water heaters, ranges, radiant heaters, and high-grade electrical

positive of the B battery is connected to the center tap o' of the primary $a'b'$ of the output transformer. Hence so far as the direct current to the plate circuits is concerned the two halves of the primary $a'b'$ are in opposition, whereas the alternating voltages across the two halves are in phase with each other. Owing to the symmetry of the connection, even harmonics caused by the curvature of the characteristics are eliminated entirely and the odd harmonics are ordinarily so small as to be negligible. With this arrangement much greater power outputs with negligible distortion can be obtained.

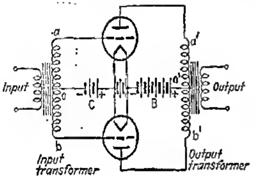

Fig. 100.—Push-pull amplifier

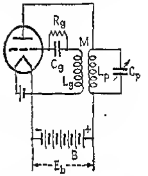

Fig. 101.—Oscillator.

A vacuum tube may become a power **oscillator** or a generator of alternating current. A tube may be made to oscillate by connecting an oscillatory circuit, consisting of inductance and capacitance in parallel, in the plate circuit. A portion of the energy of the plate circuit is fed back into the grid circuit, the direction of the connection being such that the emf due to the plate circuit is substantially in phase with the grid emf and so reinforces it. In Fig. 101 a simple oscillator is shown. The oscillatory circuit consisting of the inductance L_p and capacitance C_p in parallel is called the **tank circuit.** The frequency of oscillation $f = 1/2\pi \sqrt{L_pC_p}$. The grid circuit is coupled to the plate circuit by the mutual inductance M between L_p and L_g. A grid leak R_g prevents the accumulation of electrons on the grid which would block the tube. The load on the oscillator may be inductively coupled to L_p.

A radio wave such as is used for broadcasting is a high-frequency or r-f (radio-frequency) continuous wave having a frequency of 1,000,000 to 30,000,000 cycles per sec. This is called the **carrier wave.** In order to transmit speech and music this wave is modulated by a-f (audio-frequency) waves produced by the voice and by music. Figure 102 shows such a modulated wave. The envelope of the modulated carrier-frequency wave is the a-f wave, as shown in Fig. 102.

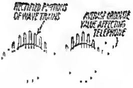

Fig. 102.—Rectified radio wave-train.

There are several methods of **modulating** the carrier wave. A common method is to introduce into the plate circuit of a tube, oscillating at the carrier frequency, an additional emf of audio frequency, the peak value of which is somewhat less than the steady plate voltage E_b. Figure 103 shows a simple plate-modulation circuit. The carrier-frequency tuned tank-cricuit L_pC_p and grid circuit are similar to those in Fig. 101. The secondary S of an audio-frequency transformer b is introduced into the plate circuit. The primary

this, the third differential; etc. These quantities are of little importance except in the case where dx = a constant. In this case

$$dy = f'(x)dx; \quad d^2y = f''(x)\cdot(dx)^2; \quad d^3y = f'''(x)\cdot(dx)^3; \ . \ . \ .$$

The first, second, third, etc., differentials are close approximations to the first, second, third, etc., differences (p. 115), and are therefore sometimes useful in constructing tables. Thus, denoting the first, second, third, etc., differences by D', D'', D''', etc., and, assuming always that dx = a constant,

$$\begin{aligned} D' &= dy + \tfrac{1}{2}d^2y + \tfrac{1}{6}d^3y + \tfrac{1}{24}d^4y + \ . \ . \ .; \quad d^3y = D''' - \tfrac{3}{2}D'''' + \ . \ . \ . \\ D'' &= d^2y + d^3y + \tfrac{7}{12}d^4y + \ . \ . \ .; \quad d^2y = D'' - D''' + \tfrac{11}{12}D'''' + \ . \ . \ . \\ D''' &= d^3y + \tfrac{3}{2}d^4y + \ . \ . \ .; \quad dy = D' - \tfrac{1}{2}D'' + \tfrac{1}{3}D''' - \tfrac{1}{4}D'''' + \ . \ . \ . \end{aligned}$$

Functions of Two or More Variables may be denoted by $f(x, y, \ . \ . \ .)$, $F(x, y, \ . \ . \ .)$, etc. The derivative of such a function $u = f(x, y, \ . \ . \ .)$ formed on the assumption that x is the only variable ($y, \ . \ . \ .$ being regarded for the moment as constants) is called the **partial derivative** of u **with respect to** x, and is denoted by $f_x(x,y)$, or $D_x u$, or $\dfrac{d_x u}{dx}$, or $\dfrac{\partial u}{\partial x}$. Similarly, the partial derivative of u with respect to y is $f_y(x,y)$, or $D_y u$, or $\dfrac{d_y u}{dy}$, or $\dfrac{\partial u}{\partial y}$.

NOTE. In the third notation, $d_x u$ denotes the differential of u formed on the assumption that x is the only variable. If the fourth notation, $\partial u/\partial x$, is used, this must not be treated as a fraction like du/dx; the $\partial/\partial x$ is a symbol of operation, operating on u, and the "∂x" must not be separated.

Partial derivatives of the second order are denoted by f_{xx}, f_{xy}, f_{yy}, or by $D_x^2 u$, $D_x(D_y u)$, $D_y^2 u$, or by $\dfrac{\partial^2 u}{\partial x^2}$, $\dfrac{\partial^2 u}{\partial x \partial y}$, $\dfrac{\partial^2 u}{\partial y^2}$, the last symbols being "inseparable." Similarly for higher derivatives. Note that $f_{xy} = f_{yx}$.

If increments Δx, Δy, (or dx, dy) are assigned to the independent variables x, y, the increment, Δu, produced in $u = f(x,y)$ is

$$\Delta u = f(x + \Delta x, y + \Delta y) - f(x,y);$$

while the **differential**, du, that is, the value which Δu would have if the partial derivatives of u with respect to x and y were constant, is given by

$$du = (f_x)\cdot dx + (f_y)\cdot dy.$$

Here the coefficients of dx and dy are the values of the partial derivatives of u at the point in question.

If x and y are functions of a third variable t, then the equation

$$\frac{du}{dt} = (f_x)\frac{dx}{dt} + (f_y)\frac{dy}{dt}$$

expresses the rate of change of u with respect to t, in terms of the separate rate of change of x and y with respect to t.

For the graphical representation of $u = f(x,y)$, see p. 178.

Implicit Functions. If $f(x,y) = 0$, either of the variables x and y is said to be an implicit function of the other. To find dy/dx, either (1) solve for y in terms of x, and then find dy/dx directly; or (2) differentiate the equation through as it stands, remembering that both x and y are variables, and then divide by dx; or (3) use the formula $dy/dx = -(f_x/f_y)$, where f_x and f_y are the partial derivatives of $f(x,y)$ at the point in question.

MAXIMA AND MINIMA

A Function of One Variable, as $y = f(x)$, is said to have a **maximum** at a point $x = x_0$, if at that point the slope of the curve is zero and the concavity

downward (see Fig. 3); a sufficient condition for a maximum is $f'(x_0) = 0$ and $f''(x_0)$ negative. Similarly, $f(x)$ has a **minimum** if the slope is zero and the concavity upward; a sufficient condition for a minimum is $f'(x_0) = 0$ and $f''(x_0)$ positive. If $f'(x_0) = 0$ and $f''(x_0) = 0$ and $f'''(x_0) \neq 0$, the point x_0 will be a **point of inflection**. If $f'(x_0) = 0$ and $f''(x_0) = 0$ *and* $f'''(x_0) = 0$, *the point* x_0 *will* be a maximum if $f''''(x_0) < 0$, and a minimum if $f''''(x_0) > 0$. It is usually sufficient, however, in any practical case, to find the values of x which make $f'(x) = 0$, and then decide, from a general knowledge of the curve, which of these values (if any) give maxima or minima, without investigating the higher derivatives.

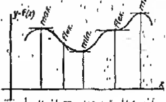

FIG. 3.

A Function of Two Variables, as $u = f(x,y)$, will have a **maximum** at a point (x_0,y_0) if at that point $f_x = 0$, $f_y = 0$, and $f_{xx} < 0$, $f_{yy} < 0$; and a **minimum** if at that point $f_x = 0$, $f_y = 0$, and $f_{xx} > 0$, $f_{yy} > 0$; provided, in each case, $(f_{xx})(f_{yy}) - (f_{xy})^2$ is positive. If $f_x = 0$ and $f_y = 0$, and f_{xx} and f_{yy} have opposite signs, the point (x_0,y_0) will be a "saddle point" of the surface representing the function (p. 178).

EXPANSION IN SERIES

The range of values of x for which each of the series is convergent is stated at the right of the series.

Arithmetical and Geometrical Series, and the Binomial Theorem. See p. 114.

Exponential and Logarithmic Series.

$$e^x = 1 + \frac{x}{1!} + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \cdots; \qquad -\infty < x < +\infty.$$

$$a^x = e^{mx} = 1 + \frac{m}{1!}x + \frac{m^2}{2!}x^2 + \frac{m^3}{3!}x^3 + \cdots; \; a > 0, \; -\infty < x < +\infty,$$

where $m = \log_e a = (2.3026)(\log_{10} a)$.

$$\log_e(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \frac{x^5}{5} - \cdots; \qquad -1 < x < +1.$$

$$\log_e(1-x) = -x - \frac{x^2}{2} - \frac{x^3}{3} - \frac{x^4}{4} - \frac{x^5}{5} - \cdots; \qquad -1 < x < +1.$$

$$\log_e\left(\frac{1+x}{1-x}\right) = 2\left(x + \frac{x^3}{3} + \frac{x^5}{5} + \frac{x^7}{7} + \cdots\right); \qquad -1 < x < +1.$$

$$\log_e\left(\frac{x+1}{x-1}\right) = 2\left(\frac{1}{x} + \frac{1}{3x^3} + \frac{1}{5x^5} + \frac{1}{7x^7} + \cdots\right); \qquad x < -1 \text{ or } +1 < x.$$

$$\log_e x = 2\left[\frac{x-1}{x+1} + \frac{1}{3}\left(\frac{x-1}{x+1}\right)^3 + \frac{1}{5}\left(\frac{x-1}{x+1}\right)^5 + \cdots\right]; \qquad 0 < x < \infty.$$

$$\log_e(a+x) = \log_e a + 2\left[\frac{x}{2a+x} + \frac{1}{3}\left(\frac{x}{2a+x}\right)^3 + \frac{1}{5}\left(\frac{x}{2a+x}\right)^5 + \cdots\right]; \qquad \begin{cases} 0 < a < +\infty \\ -a < x < +\infty \end{cases}$$

current of this transformer comes from the microphone circuit consisting of a battery B and a microphone T. The capacitance C' bypasses the carrier-frequency circuit around the secondary S of the audio-frequency transformer b. Ordinarily there is not sufficient power in the microphone circuit, so that an amplifier (Figs. 99, 100) is inserted between the microphone and the transformer b.

The ordinary sound-producing devices cannot respond to the high-frequency modulated wave such as is shown in Fig. 102, and the frequency is far too high to be audible to the human ear. It is, therefore, necessary to **demodulate** such waves in order that the receiving devices may be actuated by a-f currents similar to those used for modulating. This is called **detection.**

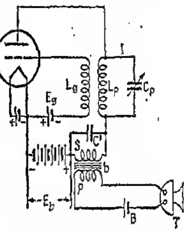

FIG. 103.—Plate modulation.

The detector must rectify or suppress one-half the wave shown dotted in Fig. 102. The high-frequency components of the rectified wave are by-passed by a capacitor such as C_p (Fig. 104). This leaves only the a-f wave shown by the solid line which is essentially the a-f wave which was transmitted. This wave then actuates the phones or speaker.

A common method of detecting is the **grid leak** shown in Fig. 104. A very high resistance R_G shunted by a small capacitance C_s is in series with the grid. The incoming carrier wave from the antenna flows through the inductance M which is in the grid circuit. Owing to the curvature of the grid-current characteristic I_g, Fig. 95, rectification is produced by the grid current flowing in C_s and R_G. Figure 104 shows a simple regenerative receiving set in which some of the plate energy is transferred to the grid circuit by mutual inductance. The plate circuit is coupled to the antenna inductance M by means of the coil M_p. A portion of the energy of the plate circuit is fed back into the grid circuit through the mutual induction of M_p on M reinforcing the received signal. This is called **regeneration.** A small capacitor C_p shunted around the phones by-passes the r-f portion of the rectified wave of Fig. 102. Two or more stages of amplification may be obtained by replacing the phones (Fig. 104) by e_g or the input of an amplifier such as is shown in Figs. 99 and 100. The phones or loudspeaker may then be connected in the plate circuit of the tube of the last stage of amplification.

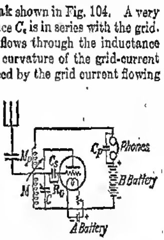

FIG. 104.—Simple regenerative receiving set.

The diode (see Fig. 93) is now in common use as a detector. It is very much less sensitive than the grid leak, but, with the high amplification now possible with heterodyne reception, this is no great disadvantage (see p. 1778).

Frequency modulation rather than the amplitude modulation just described is also being used. The amplitude of the carrier wave remains constant but its frequency is varied in accordance with the frequency of the

tion temperature produces more error in low-temperature than in high-temperature types.

Thermocouples of platinum and platinum-nickel alloy produce twice the voltage of a platinum-rhodium combination, but should not be subjected to temperatures above 2000 F. Thermoelectric couples are particularly adaptable for measuring temperatures in restricted spaces. The couples can be made thin enough to be inserted into spaces less than 1/10 in. wide. They are adaptable also for indicating temperatures of objects at a distance from the observer.

Any convenient size of wire may be used, but a good electrical contact at the junctions, and insulation of the rest of the wire, are important. Junctions may be merely twisted together; but for mechanical strength and to ensure good electrical contact in spite of oxidation, welded or soldered junctions are preferable. Insulations may be enamel, silk, cotton, or other fiber for low temperatures, and asbestos, porcelain, or other refractory for high temperatures. Pure metals should be used for thermocouple wires, and each batch of wire should be calibrated.

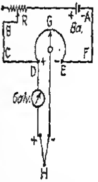

Fig. 4.—Potentiometer Circuit.

Thermocouple instruments may be either of the millivoltmeter type or of the potentiometer type. **Millivoltmeter instruments** have the advantage of being direct reading, but the readings are affected by the resistance of the leads. This difficulty is minimized by using a millivoltmeter of high internal resistance, but in any case the resistance of the thermocouple and leads should be as close as possible to that for which the instrument was calibrated. The accuracy of a high-grade millivoltmeter pyrometer with 6 in. scale and with calibrated couple and leads is usually within 1 or 2 percent of full-scale reading.

Potentiometer instruments measure the thermocouple voltage by balancing a known battery voltage against it. No current flows in the thermocouple or the lead wires, and hence their resistance does not affect the readings. A simple potentiometer circuit is shown in Fig. 4. The accuracy of thermocouple readings with a potentiometer instrument is limited by the length of the slide wire *DGE*, by the sensitiveness of the galvanometer, and by the accuracy of the wire calibration. Over-all accuracy varies from about 1 percent in commercial wide-range instruments to about 0.1 percent in the precision laboratory type used for comparative measurements with the same batch of wire.

Since the temperature measurement by a thermocouple is the difference in temperature between the two junctions, the **cold junction** or reference junction should be kept at a known temperature. In laboratory work, this is usually done by inserting the cold junction in a vacuum bottle with cracked ice and water. For industrial high-temperature work, the temperature of a cold junction buried 10 ft underground is approximately constant (within 5 F). Internal compensating devices may be built into the instrument to compensate for cold junction when the latter is at the instrument. These cold-junction **compensators** may be manually adjusted, or they may be automatic. (See p. 1721.)

Potentiometer-type industrial **temperature recorders** and controllers using thermocouples are increasing in number and variety because of their advantage of high accuracy, the usual guarantee on such instruments being less than 1 percent of full-scale deflection.

a-f wave. This method is advantageous in that quality is improved and static disturbances are in a large measure eliminated.

Radiation of Electrical Energy. When a capacitor is charged, the energy represented by the charge is stored in the dielectric medium of the capacitor; it is possible to utilize part of this energy for the purpose of radio communication. If a radio aerial or antenna (which, with the earth, forms a capacitor) is electrically charged, the stored energy will exist not only near the antenna but also out at a great distance. If an alternating voltage of high frequency is now applied between the antenna and the ground, this capacitor will be rapidly charged and discharged. If the frequency of reversal is sufficiently high, a second storage of energy in the field takes place before all the first energy stored at a great distance will have time to return to the antenna. Thus the antenna sends out successive energy impulses only a portion of which return to the system on each successive reversal; the unreturned energy impulses become ether waves the velocity of which is approximately that of light (3×10^8 m per sec in the ether or air) until intercepted or absorbed.

The **wave length** λ is the distance, usually expressed in meters, between successive wave crests. The **frequency** f of the radio wave propagation is the number of wave cycles per sec and may be obtained from the equation

$$\lambda f = 3 \times 10^8 \text{ m per sec} \tag{122}$$

For example, if the wave length is 300 m, the frequency $f = (3 \times 10^8)/(300 \times 10^3) = 1{,}000$ kilocycles (kc). **Continuous carrier waves** used in broadcasting are produced by tube oscillators which ordinarily have an oscillating circuit, composed of inductance and capacitance in parallel, connected in the plate circuit. Regenerative feedback (see Fig. 101) which sustains and reinforces the natural oscillations is obtained by coupling the plate circuit back to the grid. The antenna is coupled to the plate circuit. Modulation is accomplished by introducing the a-f emf produced by the microphone, but usually amplified, into either the grid or plate circuit (Fig. 103).

Superheterodyne Reception. In most modern receivers, superheterodyne reception is used. The method is based on the principle that a high-frequency current a may be converted to a lower frequency by superposing on it a second current of frequency a'. The frequency of the two, after passing through a detector tube, will result in an envelope frequency (see Fig. 102) equal to $a - a'$. This envelope frequency is called the beat frequency and, in receivers, the **intermediate frequency** (i-f). The intermediate frequency is obtained by a local oscillator superposing its frequency on the incoming modulated signal. If the incoming modulated frequency is 1,000 kc and the superposing frequency is 1,556 kc, the beat frequency is 1,556 − 1,000, or 556 kc. In tuning, the frequency of the local oscillator is adjusted to the incoming frequency so that the beat or intermediate frequency always remains the same. This simplifies the design of the amplifier and the circuits of the i-f stages since they can be adapted to fixed frequencies and thus operate under optimum conditions.

Superheterodyne Receiver. In Fig. 105 is shown a typical superheterodyne receiver as produced by the Browning Laboratories, Inc. For simplicity the tuning eye and details of the i-f amplifier have been omitted. The incoming signal from the antenna enters the tuned radio transformer T_1 which

Electrical-resistance thermometers employ a bridge circuit and may use a null or balance method of indication as already described for the thermocouple potentiometer. The sensitive element is a coil of fine wire, usually nickel or platinum, and the change in resistance of this wire with temperature is measured. The resistance thermometer is a highly accurate and sensitive temperature-measuring device and has the advantage of being adjustable in scale and range by the adjustment of the resistances in the bridge. A disadvantage of the resistance thermometer is its rather high cost, and its applications are usually limited to distant-reading installations in which precise measurements are needed or where the range covered is only a few degrees, as, for instance, in the accurate control of temperatures in rooms or storage spaces.

In the radiation pyrometer, a thermocouple or a thermopile is located at the focus of a lens within a lens tube (Fig. 5). When this device is sighted upon a large area such as an incandescent fuel bed or a furnace wall, the temperature attained by the thermocouple will be a function of the temperature of the object sighted upon and will be almost independent of the distance from the object, as long as the entire field of the lens is covered. The reading will depend upon the emissivity of the source of radiation. The instruments are calibrated for black-body conditions and will be approximately correct when sighted into a large furnace through a small opening. The instrument readings may be 10 to 50 percent low when sighted upon light-colored or metallic surfaces in the open. Radiation pyrometers are ordinarily used for temperatures above 1000 F, but by substituting a thermopile (series thermocouples) for a single couple the instrument may also be adapted for lower temperatures down to and including ordinarily atmospheric temperatures. The radiation pyrometer is made in both indicating and recording types and is also used as the sensitive element for control devices.

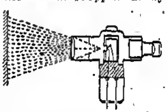

FIG. 5.—Radiation Pyrometer.

The optical pyrometer measures temperature by indicating the *brightness* of the radiation received from an object, in a narrow band of the visible spectrum. The optical pyrometer measures monochromatic radiation, and the radiation pyrometer measures total radiation. Most optical pyrometers are operated by visual comparison of the apparent brightness of the body under observation with the brightness of a standard light source. The brightness of the standard light is varied either by an absorption device such as a polarizing prism or by varying the filament current in an electric lamp. In the latter type, if the lamp filament and the object are both in focus in the same field, the filament will disappear when the current has been adjusted to give the filament the same brightness as the object. This type of instrument was used to determine the international temperature scale above the gold point. Optical pyrometers usually employ a milliammeter instrument for final reading, but potentiometer instruments are also available for more accurate work. The photoelectric pyrometer, which uses a photocell as the sensitive element, may be classed as an optical pyrometer.

The accuracy of optical pyrometers under favorable conditions may be within 1 percent. The optical pyrometer is used principally in the lower range of thermocouples, but it may be used for temperatures as low as 1200 F. When black-body conditions do not prevail, the optical pyrometer

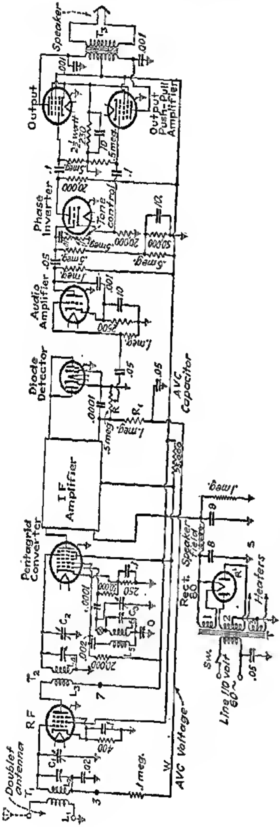

FIG. 105.—Heterodyne receiver. (Browning Laboratories, Inc.)

is subject to considerable error. For molten metals in the open, for instance, the instrument may read as much as 300 F low. Other sources of error are the presence of screens of smoke or gases and the necessity for visual setting which may introduce human error. In the determination of temperatures of luminous flames, the optical pyrometer has been applied with some success by using color screens of two different wave lengths, red and green.

Pyrometric cones are a simple and inexpensive form of fusion pyrometer. The cones are small pyramids, about 2 in. high. Each cone is prepared from mixtures of oxides and glass, to give a definite melting point. A series of cones with melting points 20 to 70 deg apart covers the range from about 1100 to 3600 F. The accuracy of the measurements is about the same as

Table 4. Melting Points of Sager Cones

No.	Deg C	Deg F	No.	Deg C	Deg F	No.	Deg C	Deg F
022	600	1110	7	1270	2320	30	1670	3040
016	750	1380	15	1435	2615	35	1770	3220
010	950	1740	20	1530	2790	39	1880	3420
02	1110	2030	26	1580	2880	42	2000 (about)	3600

the interval between successive cones, although it may not be as close because the behavior of the cones depends somewhat on the rate of heating and upon the furnace atmosphere. Pyrometric cones are used mainly in the ceramic industries.

Calibration of temperature instruments is usually accomplished by one of three methods: (1) The instrument to be calibrated may be compared with a standard instrument of suitable type. This should be done in a well-stirred fluid, with the sensitive elements of the two instruments fastened together. (2) The readings of the instrument may be determined at the melting or solidifying point of pure solid materials. The points usually used are ice, 32; tin, 449; lead, 621; zinc, 787; aluminum, 1220; sodium chloride, 1473; and copper 1982 F. Cooling curves (temperature vs. time) should be plotted and the point determined from the flat portion of the curve. (3) The readings of the instrument may be determined at the boiling points or saturation temperatures of pure liquids. Water is usually used and temperatures are taken from the steam tables. Pressures must be measured very accurately, as by dead-weight apparatus. The atmospheric boiling points of naphthalene, 425, and of sulphur, 832 F, are often included.

Accuracy of temperature measurement depends on instrument and on method of application. Almost any required degree of accuracy in scale and calibration may be obtained with glass-stem thermometers, electrical-resistance thermometers, or thermocouples, but large errors may be introduced by improper application. Most of these errors are due to: (1) stratification and poor mixing of the fluid; (2) radiation; (3) incomplete immersion or conduction. As the difference between measured temperature and ambient temperature increases, these errors become greater.

The Bureau of Standards, at Washington, D. C., will calibrate all types of thermometers and pyrometers. A fee schedule can be obtained on request. A certificate of calibration is provided by the bureau for each instrument.

Surface temperatures are best measured with thermocouples, but they may also be measured with thermometers or with radiation instruments. A thermometer pressed firmly against a hot surface and sealed with plastic

is adjusted to select the desired signal. The transformer increases the voltage impressed on the first r-f amplifier tube (RF). The signal is not only amplified in the plate current of the r-f tube but also by the effect of the tuned r-f transformer (T_2) which also couples the signal into a mixer tube (pentagrid converter). The local frequency is also fed into the converter by the oscillator O. This frequency is mixed with that of the modulated incoming signal, and several frequencies are produced in the plate circuit of the converter, but all the frequencies except the difference or beat frequencies between the oscillator and the incoming frequencies are eliminated by a tuned i-f transformer in the i-f amplifier. This difference or intermediate frequency is constant and varies in different circuits from 456 to 465 kc. The i-f amplifier amplifies the power of the i-f frequency which has all the modulation characteristics of the incoming signal. In addition, the amplifier adds greatly to the selectivity of the set because of its tuned coupled circuits. Tuning the incoming signal is accomplished by the simultaneous adjustment of the three variable capacitors C_1 and C_2, and C_3 which are all "ganged" on the same shaft.

After the i-f amplifier, the i-f signal is rectified by the diode detector (p. 1773), and the resulting audio frequency flows through a resistor R usually of the potentiometer type. This resistance acts as volume control. The audio frequency developed across the resistance is amplified by the audio amplifier and phase inverter. The phase inverter also provides the two suitable feed potentials for the push-pull amplifier. The output of the amplifier is supplied to the primary of the a-f transformer T_3 and the speaker is connected to its secondary.

Automatic volume control (a-v-c), is obtained by the voltage developed across the 1 meg resistance R_1 which charges the 0.05-microfarad a-v-c capacitor. This voltage is fed back over the wire W to terminal 3 and gives a more or less negative bias to the grids of the r-f and i-f tubes, according to the strength of the incoming signal.

The power supply system is shown at S. The current from the 110-volt 60-cycle supply goes into the primary of a 60-cycle transformer T. There are three secondaries. The top secondary 1, usually rated at 5 volts, supplies the filament of the rectifier tube R', this filament also acting as cathode. In the intermediate secondary 2, usually rated at 350 volts max to the grounded center tap, the outer terminals are connected to the two anodes of the rectifier tube R'. The lowest secondary 3 supplies the heaters of the tubes in the set and is rated at 6.3 volts. It also has a grounded center tap which fixes the potentials of the heaters. To the right of the rectifier is a filter in which the speaker field is used as a series reactance. The rectifier delivers direct current for the B or plate voltage of 250 volts. A potential of 90 volts is obtained for the screen grids by means of the drop in the 25,000-ohm resistance.

material will read low, the error varying from about 5 F when the true temperature is 50 F above ambient, to 20 F when the temperature is 200 F above ambient. More accurate surface-temperature measurements may be made with thermocouples, either attached to the surface with adhesive or imbedded in cement in a shallow groove. Fine wires (24 to 40 gage) should be used, and the *insulated lead wires should be in contact with the surface* for some distance from the couple. For high temperatures or for quick readings from inaccessible surfaces, a radiation thermopile or a radiation pyrometer may be used.

PRESSURE MEASUREMENTS

The preferred method of measuring **barometric pressure** is by means of a mercury column with a brass scale. Standard barometer reading at sea level *is 29.92 in. of mercury at 32 F or 30 in. at 58 F.* **Gage pressure** is the pressure indicated by a gage, above atmospheric. **Vacuum** is pressure below atmospheric and is commonly expressed in inches of mercury. **Absolute pressure** is the sum of gage and barometric pressures.

Table 5. Barometer Corrections for Temperature

To correct the observed reading of a mercury barometer or U tube to the 32 F standard, add or subtract the following values in inches of mercury.

Temperature of mercury column, deg F	Observed reading of mercury column, in. of mercury						
	20	22	24	26	28	30	32
−20	+0.09	+0.10	+0.11	+0.11	+0.12	+0.13	+0.14
0	+0.05	+0.06	+0.06	+0.07	+0.07	+0.08	+0.08
20	+0.02	+0.02	+0.02	+0.02	+0.02	+0.02	+0.02
40	−0.02	−0.02	−0.02	−0.03	−0.03	−0.03	−0.03
60	−0.06	−0.06	−0.07	−0.07	−0.08	−0.08	−0.09
80	−0.09	−0.10	−0.11	−0.12	−0.13	−0.14	−0.15

CONTENTS

The **corrected barometer reading** is the observed reading corrected for temperature, gravity, elevation, and instrument calibration. For absolute pressures considerably above atmospheric, the barometer reading as observed is usually sufficiently accurate. If low absolute pressures are to be determined, such as the exhaust pressure of a condensing steam turbine, all barometer corrections should be applied. Barometer corrections for temperature, gravity, and elevation are given in Tables 5, 6, and 7. The A.S.M.E. Power Test Codes require these three corrections for accurate work and require in addition a barometer calibration correction. The Code specifies that this *barometer calibration* is to be made by correcting the observed barometer reading (Tables 5 and 6) and reducing the result to sea level (Table 7). The difference between this result and the "weather-map reading" for the location of the observed barometer, obtained from the U.S. Weather Bureau, is the calibration correction. *Barometric pressures reported by the Weather Bureau* have already been corrected to 32 F and reduced to sea level. The reading of a local barometer for purposes of calibration should be made at the same time that the Weather Bureau takes its readings. These readings are taken at 8 A.M. and 8 P.M., 75th meridian time (E.S.T.).

Table 7. Barometer Corrections for Elevation

To correct the observed reading of a mercury barometer or U tube to the equivalent reading at a higher elevation, subtract the following values in inches of mercury for each 100 ft difference in elevation (add for lower elevation).

Mean elevation ft	Mean atmospheric temperature, deg F						
	−20	0	20	40	60	80	100
0	0.13	0.12	0.12	0.11	0.11	0.10	0.10
1,000	0.12	0.12	0.11	0.11	0.10	0.10	0.10
2,000	0.12	0.11	0.11	0.10	0.10	0.10	0.09
3,000	0.11	0.11	0.10	0.10	0.10	0.09	0.09
4,000	0.11	0.10	0.10	0.10	0.09	0.08	0.08
5,000	0.10	0.10	0.10	0.09	0.09	0.08	0.08
6,000	0.10	0.10	0.09	0.09	0.08	0.08	0.08
7,000	0.10	0.09	0.09	0.09	0.08	0.08	0.08

Following is a typical example of a barometer correction:

The barometer reading at the center line of the turbine casing in a power plant at Boston, Mass. is 29.80 in. of mercury. Barometer temperature 75 F. Barometer cistern located 16 ft below turbine center line. The temperature correction (Table 5) is −0.13 in. of mercury; the gravity correction (Table 6) is −0.01 in. of mercury; and the elevation correction (Table 7) is −0.02 in. of mercury. The calibration correction determined from Weather Bureau comparison is assumed to be +0.04 in. of mercury. The total net correction is the sum of these four or −0.12 in. of mercury. The barometric pressure at the turbine center line is then 29.68 in. of mercury.

Aneroid barometers are sometimes used on account of their compactness and portability. The aneroid is an exhausted chamber with corrugated diaphragm walls, the collapsing of which is resisted by a spring. The deflections of the diaphragms against the spring are indicated or recorded by a lever mechanism. A recording aneroid barometer is called a **barograph.** Because of hysteresis and aging, the aneroid barometer should be calibrated frequently against a mercury barometer. The aneroid barometer is also made in the more accurate null type in which the diaphragm is brought back to an initial position by changing the tension of the loading spring. This same motion rotates the scale to give the new reading.

Absolute-pressure gages may be made by using a mercury barometer tube as a vacuum gage. The vacuum connection is made at the mercury

cistern, or the barometer tube may be turned into a U and the vacuum connection made at the open end. Since the pressure in the closed end is practically zero, the mercury-level differential gives absolute pressure directly. Recording absolute-pressure gages of this type are available, the recording function being obtained by mounting a float in the high-pressure end of the U-tube barometer. Recording absolute-pressure gages are also made by differentially connecting an aneroid barometer and a spring-type vacuum gage.

Manometers are U-shaped tubes, either vertical or inclined, filled with a liquid of known density. The difference in pressure at the two ends of the U is determined from the displacement of the liquid. A manometer with one end open to atmosphere gives a direct reading of equivalent gage pressure or vacuum, *i.e.*, pressure above or below atmospheric. The U-tube manometer (Fig. 6) may be used in either upright or inverted position. The air or indicating liquid in the top of the inverted U tube must be trapped before inverting the instrument, or it may be pumped in against the existing pressure. A correction must be made for the difference in heights of the columns of indicating liquid above the manometric fluid in the two legs. Even with air above the manometric fluid, a correction should be made at high pressures—the density of air at 100 lb. pressure is about 0.01 of the density of water.

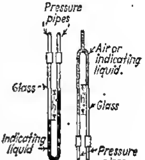

FIG. 6.—Upright and Inverted U-tube Manometers.

A manometer is easier to read if a large chamber or cistern is used as one leg of the U tube, as shown in Fig. 7. The readings may then be taken on the small-bore side only, with proper compensation for the slight change in level in the cistern. A cistern-type manometer with the small-bore tube inclined instead of vertical is often called a **draft gage**, because it is the instrument usually used in test work for measuring chimney draft. The increase in length of scale for a given vertical rise results in a more sensitive instrument. The multiplying factor for the scale of an inclined manometer or draft gage is equal to the cosecant of the angle the tube makes with the horizontal. The usual multiplying factors are from 2 to 1 to 10 to 1, but a multiplication of 20 to 1 may be used if the instrument is accurately leveled. The most common errors in the readings of inclined manometers are due to faulty setting of the zero of the scale or to inaccurate leveling of the instrument. They should always be calibrated by comparison with a micromanometer, preferably a hook gage device with water as fluid.

FIG. 7.—Cistern-type Manometer.

The **two-fluid manometer** is also a more sensitive gage than a simple U tube. Two fluids of different specific gravity are used, such as oil and water or mercury and oil. A two-fluid manometer for gas pressures is shown in Fig. 8. One of the cisterns may be open to the atmosphere. The heavier liquid may be either water or alcohol diluted with water to make its specific gravity only slightly greater than that of the lighter liquid (kerosine). The alcohol may be colored with an aniline dye that is insoluble in the kerosine. If the specific gravity of the dilute alcohol is 0.83 and that of the kerosine is

MECHANICAL MEASUREMENTS

Errors in Measurement. An error is the difference between the observed value and the true value and may be expressed as a percentage of either. Errors may be due to the instrument, the method, or the observer. **Instrument errors** may be reduced by repeated calibration. Certain inaccuracies may be unavoidable, such as those due to the aging of glass or of magnets. Errors may be due to sluggishness or lack of sensitiveness, but sensitiveness beyond the requirements of the desired accuracy may result in slowness of operation.

The scales on most indicating instruments are 2½ to 6 in. long. Instrument and chart graduations closer than 20 to the inch are difficult to read. With these physical limitations, an accuracy of 1 or 2 percent of full scale is the best that can be expected with many common instruments. To determine the difference between two readings 1 in. apart on an instrument scale, within an accuracy of 1 percent, calls for readings accurate to a linear distance of 1/200 in. which is not possible without a magnifying lens. **Errors in method** of application or use of instruments are sometimes very large. **Personal errors** and blunders are minimized by the training and experience of observers. A lack of knowledge of instrument technique may introduce errors of considerable magnitude. **Accidental errors** still remain when all controllable conditions are kept as near constant as possible. Such errors may be treated by the laws of probability and the theory of least squares.

Relative accuracy of observations is usually much higher than absolute accuracy. Many instruments and methods are quite satisfactory for measuring *differences* in temperature, velocity, rate of flow, etc., but are not suitable for determining absolute values.

TEMPERATURE MEASUREMENTS

Instruments for measuring temperature are classified in Table 1, which also gives the temperature range and the degree of accuracy usually obtainable.

For temperatures below 1000 F, the choice is among a mercury thermometer, a thermocouple, a gas- or vapor-filled pressure-gage thermometer, and an electrical-resistance thermometer. For temperatures above 1000 F, the choice is among a thermocouple, a radiation pyrometer, and an optical pyrometer.

Liquid-in-glass thermometers are usually filled with mercury and have a vacuum in the capillary. Since the freezing point of mercury is −38 F, alcohol or pentane is used for very low temperatures. To measure temperatures above 600 F, the mercury is sealed under pressure, using nitrogen or carbon dioxide in the capillary. With special glass, this gives a range up to 1000 F, although difficulties from stem distortion may be encountered above 900 F. For greater ease in reading, the glass stem may be made with colored inserts, a colored background, or with a magnifying-lens front. Glass-stem thermometers are graduated for complete immersion of bulb and stem unless partial immersion is specified. When the stem of a total-immersion ther-

0.79, then the difference of gas pressures in inches of water is $H(0.83 - 0.79) = 0.04H$, *i.e.*, the gage shows a difference 25 times greater than a U tube with water. A small correction may be necessary for the difference in level of the surfaces in the two cisterns, but by making the cisterns large this correction may be avoided. The glass columns should not be over $\frac{3}{16}$ in. in internal diameter to avoid irregular meniscus.

The manometer liquids most commonly used are *mercury, water, oil, alcohol*. Table 8 gives the densities of these liquids at 32 and 70 F and also the conversion factors to change manometer readings into pressure in pounds per square inch.

Inverted-bell manometers are widely used for permanently mounted draft gages, and they operate like a gasometer storage tank. Functionally, they are modified U-tube manometers, the inside of the bell acting as one leg of the manometer (see Fig. 9). Vertical displacement of the bell is balanced by a weight, and the displacement may be greatly magnified by a lever mechanism and a long pointer. Thus a large easy-reading scale may be used.

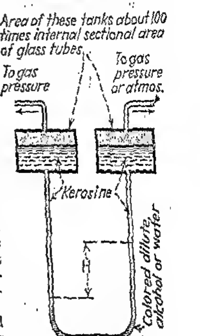

FIG. 8.—Differential Manometer.

Micromanometers are manometers fitted with some precision reading or magnifying device. They are usually graduated in increments of 0.001 in. of water, though they may in some cases be sensitive to 0.0001 in. Most micromanometers are of the inclined-tube type. The **Wahlen gage** is a two-fluid inclined-tube micromanometer, using fluids of very nearly the same density. (For details of construction see *Univ. Illinois, Eng. Expt. Sta. Bull.* 120.)

A **hook gage** is a means for accurately measuring a liquid level, and it is sometimes applied to manometers, in order to obtain more accurate readings

Table 8. Manometer Liquids and Conversion Factors

Manometer liquids	Specific gravity relative to water at 39 F[a]		To convert in. of liquid to lb per sq in. multiply by	
	Manometer temp 70 F	Manometer temp 32 F	Manometer temp 70 F	Manometer temp 32 F
Mercury	13.543	13.595	0.489	0.491
Water	0.9980	......	0.0361	
Kerosine (44–46 deg. A.P.I.)	0.799	0.812	0.0289	0.0293
Red draft gage oil (approx)	0.820	0.835	0.0296	0.0301
Methyl (wood) alcohol	0.790	0.810	0.0285	0.0293
Ethyl (grain) alcohol	0.789	0.805	0.0285	0.0291
Gasoline (58–60 deg. A.P.I.)	0.739	0.752	0.0267	0.0270

[a] Density of water at 39 F, 62.43 lb per cu ft.

mometer is only partially immersed, as in a thermometer well, a **correction for stem exposure** must be made. The A.S.M.E. Test Codes recommend the attachment by asbestos thread of a second thermometer with its bulb near the middle of the exposed portion of the stem and corrections made by the formula $K = 0.000088D(t_1 - t_2)$, where D is the number of degrees of exposed filament, t_1 the reading of the main thermometer, and t_2 the reading of the attached thermometer. When the stem is cooler than the bulb, the correction K, in degree Fahrenheit, is added.

Table 1. Range and Accuracy of Thermometers and Pyrometers

Type	Range, deg F	Accuracy, deg F
Glass thermometers:		
Ordinary glass, mercury-filled	−38 to 760	0.5 to 2
Jena glass, mercury and nitrogen-filled	−38 to 1000	2 to 10
Quartz glass and borosilicate glass, mercury and nitrogen-filled	−38 to 950	2 to 10
Ordinary glass, alcohol-filled	−95 to 150	1 to 2
Ordinary glass, pentane-filled	−300 to 70	1 to 2
Pressure-gage thermometers:		
Vapor-pressure type:		
Alcohol-filled	200 to 400	2 to 10
Ether-filled	*100 to 300*	*2 to 10*
Sulphur-dioxide-filled	20 to 250	2 to 10
Liquid-filled or gas-filled type:		
Alcohol-filled	−50 to 300	2 to 10
Mercury-filled	−38 to 1000	2 to 10
Nitrogen-filled	−200 to 1000	2 to 10
Bi-metallic thermometer	300 to 1000	Uncertain
Electrical resistance thermometer	*−400 to 1800*	*0.005 to 5[a]*
Thermocouple pyrometers:		
Base-metal	300 to 2000	2 to 20[a]
Rare-metal	300 to 2800	2 to 20[a]
Optical pyrometers	1400 up	20 for black-body conditions
Radiation pyrometers	*1000 up*	*20 to 30 for black-body conditions*
Fusion pyrometers	1100 to 3600	20 in best makes
Calorimetric devices	100 to 2500	Uncertain
Color-temperature charts	800 to 2900	Uncertain

[a] Depends upon indicating instrument.

External pressure corrections should be applied to glass-stem thermometers when the bulb is exposed to high pressures. The correction is about 0.01 F per lb per sq in. in the case of a high-grade thermometer with a bulb wall thickness of 0.5 to 0.7 mm.

Thermometer wells similar to the finned well of Fig. 2 and Table 2 are prescribed by the A.S.M.E. Codes for measuring the temperature of a gas or of a superheated vapor in a pipe. When the pipe contains a saturated vapor only, or a flowing liquid, the fins may be omitted. Thermometer wells should be filled with a non-viscous liquid of high conductivity. Water, alcohol, or kerosine may be used for low temperatures, mercury or oil for higher temperatures, and tin or solder for temperatures above 600 F. Exposed parts should be insulated.

For industrial applications, glass-stem thermometers with special metal protecting cases are available. In all applications, the direct immersion of the thermometer in the fluid is preferred, but where this is impracticable the bulb should at least be in good thermal contact with the wall of the thermometer well.

In **solid-expansion thermometers,** the sensitive element is a bimetallic strip or coil which is fixed at one end. The quality of these instruments

than are possible by visual observation of a meniscus. The essential feature of a hook gage is the piercing of the liquid surface by a sharp-pointed hook, raised from below. Just before the point pierces the skin of the liquid surface, a pimple is seen to rise above the point. The point is lowered until this pimple is barely discernible, and the position of the point, *i.e.*, the liquid level, is then read by means of a vernier or a micrometer screw. The standard Fan Test Code of the A.S.H.V.E. requires that inclined manometers used in fan tests be calibrated in place against a water-filled hook gage reading to 0.001 in. of water. See p. 281.

Commercial manometers are available with indicating, recording, and integrating devices. These devices are actuated by the level of the liquid in the manometer (usually mercury) using floats and lever arrangements or electrical or magnetic arrangements. It is thus possible to make the manometers distant reading.

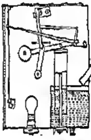

FIG. 9.—Inverted-bell Manometer.

Dead-weight Gages depend on balancing a known weight against the pressure to be measured. The weight is supported on a piston, and the pressure is usually transmitted to the bottom of the piston by oil, which also acts as seal and as lubricant for the piston. The piston is rotated with respect to the cylinder to prevent friction errors. Dead-weight gages are used as **gage testers** for calibrating other gages. They are also used in precision test work and for master gages in the boiler rooms of large steam stations. By spring loading a dead-weight gage, a very sensitive pressure gage for a small range may be obtained, as, for instance, a gage that reads 575 to 625 lb per sq in. for a 600 lb steam boiler; such gages are made distant reading by electric telemetering. The dead-weight gage is obtainable in any range from manometer pressures to 50,000 lb per sq in.

Bourdon-tube gages are the most common of the spring-type gages. A Bourdon tube is elliptical in cross section, bent into a circular arc. When internal pressure is applied to such a tube, it tends to straighten out. Single-spring and double-spring arrangements are used in pressure gages. A variety of Bourdon gages are available, from the common production-type gage selling at a dollar or two, to the special precision gage with machined alloy-steel tube, hardened sector, pinion, and bearings, and special adjustments including a micro zero setting. Such precision gages are accurate to about 0.25 percent of full-scale reading and are made in large sizes, usually 10 to 16 in. For accurate work, a Bourdon gage should be calibrated frequently on a dead-weight gage tester. In use, the gage should be protected from vibration, from excessive temperatures, and from corrosive liquids or gases. Gages of special materials are available, in case corrosion is a problem. For ammonia, an all-steel gage is required.

Diaphragm and **bellows gages** are used mainly for low pressures, though metallic-bellows gages are available for pressures as high as 200 lb per sq in. The diaphragm or bellows gage provides larger forces for actuating the indicating or recording mechanism than the bent-tube gage and, consequently, is especially suitable for measuring pressures in the manometer range or in the low Bourdon-type ranges. **Slack-diaphragm gages** use soft elastic diaphragms of leather, treated cloth, or rubber, externally spring loaded. Several commercial makes of draft gages operate on this principle and have the advantage of not involving any liquid or requiring accurate leveling.

varies from the domestic room thermometers costing but a few cents to laboratory thermometers of fair precision. Solid-expansion thermometers should be checked frequently, because the zero point may change with use.

Pressure-gage thermometers are the least expensive of the distant-reading and recording types and are widely used in industrial service. The operating fluid may be a gas, vapor, or liquid; the fluid bulb is connected by capillary tubing to a pressure-spring displacement unit, as shown in Fig. 3. Inexpensive units used for automobile instrument boards have an accuracy of only 5 to 10 percent of full-scale reading, while larger units for industrial and laboratory service may have a maximum error of 1 to 3 percent of full-scale reading. If the capillary and the spring tube of a gas- or liquid-filled unit are subjected to ambient temperatures widely different from that for which the instrument was calibrated a large error may result unless some compensating device is used; the vapor-pressure type (Fig. 3) is not affected by these variations. The sensitive bulb of a pressure-gage thermometer is comparatively large in size and is subject to radiation effects when used in air or gas; these radiation errors are minimized through the use of stainless steel bulbs or sockets, but it is best to locate the bulb where it will not "see" surfaces much hotter or colder than the temperature being measured. If temperatures beyond the range of the instrument are likely to be encountered, some type of overrange protection should be built into the instrument.

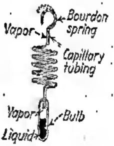

FIG. 3.—Vapor-pressure thermometer.

Thermocouples are pairs of wires, of dissimilar metals, connected at both ends. When the two junctions are subjected to different temperatures, an

MEASUREMENTS OF TIME AND SPEED

The ordinary spring-wound clock or stop watch is the most common instrument for measuring time, but with the accurate frequency control on electric utility systems, synchronous-motor timing devices are becoming more common. System frequency is usually held so close to 60 cycles per sec that synchronous timers are sufficiently accurate for all engineering uses.

High-speed studies may require more refined methods of timing than the ordinary stop watch or electric clock. By the use of the oscillograph and the motion-picture camera, moment-to-moment conditions in a rapidly changing system can be studied in detail. For measuring very short time intervals or longer intervals very accurately, both mechanical and electrical devices are available. The most common mechanical device is the tuning fork, usually arranged to draw a sine curve. By using forks of different frequencies, almost any desired subdivision of the second may be obtained. Chronographs may employ electromagnets to vibrate a pen or pencil, or the paper may be punctured at regular intervals by a high-tension electric spark produced by a mechanical interrupter. In a-c **cycle counters**, the ultimate division is a single a-c cycle.

Starting and stopping errors are the chief inaccuracies in timing speed measurements. The instruments should be mechanically or electrically connected so that a single impulse, such as the throwing of a switch or lever, will start both the timing and the displacement or counting instrument. Long runs are also desirable. An error of a single scale division on a ⅕ sec stop watch amounts to 1.33 percent error in a 15 sec run but only 0.11 percent error in a 3 min run.

Rotational speeds are measured by the counter, the tachometer, and the stroboscope. Photoelectric methods are used for certain types of counting. **Mechanical speed counters** may be either of the rotating or of the oscillating ratchet type. The rotating counter with a magnetic clutch connector and a synchronous electric timer operated by the same switch is probably the most accurate of the common speed-measuring devices and is used for calibrating other instruments. The rotating continuous counter may have direct-reading wheels of the cyclometer type or may operate dials or pointers through a gear train. The oscillating or stroke counter is adapted for low speeds only; rotary counters may be obtained for high-speed work, up to 5,000 rpm or more, but the speed limit for which a counter was designed should be ascertained before it is used for high speeds.

Hand counters are widely used in test work. These are small rotating counters arranged to be driven by a friction tip inserted in the shaft center or by some form of positive engagement. A hand counter or tachometer fitted with a surface wheel for obtaining linear surface speeds is sometimes called a **cutmeter**, because such instruments are used for determining cutting speeds in machine-tool work. Combined counter and stop-watch instruments are available in which the timing and the counting functions are started and stopped simultaneously; they are capable of giving accurate speed measurement with a hand instrument.

Tachometers give a direct and continuous indication of speed in rpm. They may be either permanently mounted or hand type and may be both indicating and recording. Their accuracy is affected by the mechanical condition of the instrument; frequent calibrations are required for accurate work. The force produced by the rotation is balanced against a calibrated spring or against the force of gravity. Electric and fluid-pump tachometers

electrical potential is set up between them. This voltage is almost directly proportional to the temperature difference, and hence a voltage-measuring instrument placed in the circuit will measure temperature. Table 3 gives

the emf generated at various temperatures with commonly-used thermocouples. The couples are not recommended for use near the maximum temperature unless protected by a metal or ceramic tube. In no case should they be used above the maximum temperature indicated. For use at temperatures below 500 F, copper-constantan (a copper-nickel alloy) thermocouples are best because of their resistance to corrosion and consequent long life with stable calibration. Between 500 F and 1200 F iron-constantan thermocouples are best and can be used in either an oxidizing or reducing atmosphere. The rusting of the iron at low temperatures in the presence of moisture make iron-constantan less desirable than copper-constantan for temperature ranges in which the latter can be used. For high-temperature work platinum-platinum 10 percent rhodium thermocouples should be used. In a reducing atmosphere the couples must be thoroughly protected. A slightly more sensitive high-temperature thermocouple consists of platinum-platinum 13 percent rhodium. Chromel-alumel thermocouples are more stable than iron-constantan but less stable than platinum-platinum rhodium thermocouples for high-temperature work.

The material used for the construction of protecting tubes is dictated by the maximum temperature encountered and the corrosive action to which it will be subjected. Iron or steel tubes can be used up to about 1300 F. The use of nickel-chromium alloy protecting tubes extends the temperature range up to about 2000 F. For higher temperatures various refractory materials (quartz, alundum, etc.) can be used. Silicon carbide tubes are especially resistant to the action of flame up to about 3000 F.

Pyrometers of the cheaper metals often have the leads of the same metals as the couples, so that the cold junction is at the terminals of the galvanometer, and the leads are usually long enough to permit the instrument being placed where the temperature can be maintained at about normal "room" temperatures. Variation in the cold-junction temperature from the calibra-

have the advantage of being adapted to distant reading. Hand tachometers with several sets of change gears are available, so that a wide range of speeds can be accurately measured with a single instrument.

The **stroboscope** utilizes the phenomenon of persistence of vision when an object is viewed intermittently. By viewing a cyclic motion at the same point in the cycle each time, the object appears to be motionless. By changing the frequency slightly, slow-motion in either direction can be obtained. The older stroboscopes interrupted the vision either by a tuning-fork arrangement or by a rotating perforated disk or cylinder. The neon-tube stroboscope is now displacing the other types, because of its convenience and because it is adapted to stroboscopic photography.

Neon-tube stroboscopes are commercially available for speed measurement, with indicating dials calibrated throughout the range from 700 to 14,000 rpm (the "Strobotac," General Radio Co.). These instruments are especially valuable where it is inconvenient to make a connection or contact with the rotating shaft or for light-powered machinery where the load to drive a speed-measuring instrument would affect the operation of the machine.

Speed measurements by the stroboscope necessitate its calibration in terms of frequency. The frequency of a neon-tube stroboscope is conveniently checked against the frequency of an a-c power system. The common neon-glow lamp obtainable at retail stores for a few cents may be operated from any ordinary utility power source for illuminating a stroboscopic disk. This apparatus can then be used for calibrating tachometers at the 60 cycle synchronous speeds, 3,600, 1,800, 1,200 rpm, etc. A satisfactory stroboscopic disk for such calibrations may be made from a 3 in. black disk bearing a single radial white line of some width. At 3,600 rpm this disk will show two lines, at 1,800 rpm it will show 4 lines, at 1,200 rpm it will show 6 lines. When the flash interval is neither a multiple nor an even fraction of the rpm, the geometric figure will appear to be moving.

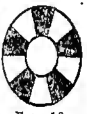

FIG. 10.—Stroboscopic Figure.

If it is desired to hold a rotating machine very exactly at a constant speed, this may be accomplished by constructing a disk with a number n of equally spaced black sectors as in Fig. 10. With 60 cycle current, the disk will appear to be stationary for any speed which is a multiple K of $120/n$. The actual speed may be determined by the use of an ordinary tachometer. The stroboscope would be used to permit close adjustment of the speed to the desired constant value. This arrangement can be used only for speeds of $120K/n$ where K and n are any integers.

WEIGHING DEVICES

The following devices are ordinarily used in engineering work to determine weight:

	Usual capacity, lb	Probable sensitiveness, lb.
Platform scales	100–2,000	1/16–1/2
Spring balances	5–200	1/16–1
Torsion balances	10	1/32–1/4
Automatic scales:		
1. Pendulum type	50	1/32
2. Spring type	200	1/16
Chemical balances	50 (g)	1 in 100,000

Series for the Trigonometric Functions. In the following formulæ, *all angles must be expressed in radians.* If D = the number of degrees in the angle, and x = its radian measure, then $x = 0.017453\ D$.

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots; \qquad -\infty < x < +\infty.$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \frac{x^8}{8!} - \dots; \qquad -\infty < x < +\infty.$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \frac{62x^9}{2835} + \dots; \qquad -\pi/2 < x < +\pi/2.$$

$$\cot x = \frac{1}{x} - \frac{x}{3} - \frac{x^3}{45} - \frac{2x^5}{945} - \frac{x^7}{4725} - \dots; \qquad -\pi < x < +\pi.$$

$$\sin^{-1} y = y + \frac{y^3}{6} + \frac{3y^5}{40} + \frac{5y^7}{112} + \dots; \qquad -1 \leqq y \leqq +1.$$

$$\tan^{-1} y = y - \frac{y^3}{3} + \frac{y^5}{5} - \frac{y^7}{7} + \dots; \qquad -1 \leqq y \leqq +1.$$

$\cos^{-1} y = \frac{1}{2}\pi - \sin^{-1} y; \quad \cot^{-1} y = \frac{1}{2}\pi - \tan^{-1} y.$

Series for the Hyperbolic Functions (x a pure number).

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \dots; \qquad -\infty < x < \infty.$$

$$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \dots; \qquad -\infty < x < \infty.$$

$$\sinh^{-1} y = y - \frac{y^3}{6} + \frac{3y^5}{40} - \frac{5y^7}{112} + \dots; \qquad -1 < y < +1.$$

$$\tanh^{-1} y = y + \frac{y^3}{3} + \frac{y^5}{5} + \frac{y^7}{7} + \dots; \qquad -1 < y < +1.$$

General Formulæ of Maclaurin and Taylor. If $f(x)$ and all its derivatives are continuous in the neighborhood of the point $x = 0$ (or $x = a$), then, for any value of x in this neighborhood, the function $f(x)$ may be expressed as a power series arranged according to ascending powers of x (or of $x - a$), as follows:

$$(1)\ f(x) = f(0) + \frac{f'(0)}{1!}x + \frac{f''(0)}{2!}x^2 + \frac{f'''(0)}{3!}x^3 + \dots + \frac{f^{(n-1)}(0)}{(n-1)!}x^{n-1} + (P_n)x^n. \quad \text{(Maclaurin.)}$$

$$(2)\ f(x) = f(a) + \frac{f'(a)}{1!}(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \frac{f'''(a)}{3!}(x-a)^3 + \dots + \frac{f^{(n-1)}(a)}{(n-1)!}(x-a)^{n-1} + (Q_n)(x-a)^n. \quad \text{(Taylor.)}$$

Here $(P_n)x^n$, or $(Q_n)(x-a)^n$, is called **the remainder term**; the values of the coefficients P_n and Q_n may be expressed as follows:

$P_n = \{f^{(n)}(sx)\}/n! = \{(1-t)^{n-1}\ f^{(n)}(tx)\}/(n-1)!$

$Q_n = \{f^{(n)}[a + s(x-a)]\}/n! = \{(1-t)^{n-1} f^{(n)}[a + t(x-a)]\}/(n-1)!$

where s and t are certain unknown numbers between 0 and 1; the s-form is due to Lagrange, the t-form to Cauchy.

The error due to neglecting the remainder term is less than $(\bar{P}_n)x^n$, or

$(\overline{Q}_n)(x-a)^n$, where $\overline{P}_n$, or $\overline{Q}_n$, is the largest value taken on by P_n, or Q_n, when s or t ranges from 0 to 1. If this error, which depends on both n and x, approaches 0 as n increases (for any given value of x), then the general-expression-with-remainder becomes (for that value of x) a convergent infinite series.

The sum of the first few terms of Maclaurin's series gives a good approximation to $f(x)$ for values of x near $x=0$; Taylor's series gives a similar approximation for values near $x=a$.

Reversing a Series. If $y = x + bx^2 + cx^3 + dx^4 + ex^5 + \ldots$, then $x = y - by^2 + (2b^2-c)y^3 - (5b^3-5bc+d)y^4 + (14b^4-21b^2c+6bd+3c^2-e)y^5 + \ldots$, provided the latter series is converging.

Fourier's Series. Let $f(x)$ be a function which is finite in the interval from $x = -c$ to $x = +c$ and has only a finite number of discontinuities in that interval (see note below), and only a finite number of maxima and minima. Then, for any value of x between $-c$ and c,

$$f(x) = \tfrac{1}{2}a_0 + a_1\cos\frac{\pi x}{c} + a_2\cos\frac{2\pi x}{c} + a_3\cos\frac{3\pi x}{c} + \ldots$$
$$+ b_1\sin\frac{\pi x}{c} + b_2\sin\frac{2\pi x}{c} + b_3\sin\frac{3\pi x}{c} + \ldots$$

where the constant coefficients are determined as follows:

$$a_n = \frac{1}{c}\int_{-c}^{c} f(t)\cos\frac{n\pi t}{c}\,dt,\quad b_n = \frac{1}{c}\int_{-c}^{c} f(t)\sin\frac{n\pi t}{c}\,dt.$$

In case the curve $y = f(x)$ is symmetrical with respect to the origin, the a's are all zero, and the series is a sine series. In case the curve is symmetrical with respect to the y-axis, the b's are all zero, and a cosine series results. (In this case, the series will be valid not only for values of x between $-c$ and c, but also for $x = -c$ and $x = c$.) A Fourier's series can be integrated term by term; but the result of differentiating term by term will in general not be a convergent series.

NOTE. If $x = x_0$ is a point of discontinuity, $f(x_0)$ is to be defined as $\tfrac{1}{2}[f_1(x_0) + f_2(x_0)]$, where $f_1(x_0)$ is the limit of $f(x)$ when x approaches x_0 from below, and $f_2(x_0)$ is the limit of $f(x)$ when x approaches x_0 from above.

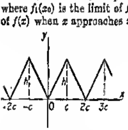

FIG. 4.

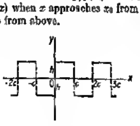

FIG. 5.

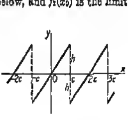

FIG. 6.

Examples of Fourier's Series. If $y = f(x)$ is the curve in Figs. 4, 5, and 6,

then, in Fig. 4, $\quad y = \dfrac{h}{2} - \dfrac{4h}{\pi^2}\left(\cos\dfrac{\pi x}{c} + \dfrac{1}{9}\cos\dfrac{3\pi x}{c} + \dfrac{1}{25}\cos\dfrac{5\pi x}{c} + \ldots\right)$,

in Fig. 5, $\quad y = \dfrac{4h}{\pi}\left(\sin\dfrac{\pi x}{c} + \dfrac{1}{3}\sin\dfrac{3\pi x}{c} + \dfrac{1}{5}\sin\dfrac{5\pi x}{c} + \ldots\right)$,

in Fig. 6, $\quad y = \dfrac{2h}{\pi}\left(\sin\dfrac{\pi x}{c} - \dfrac{1}{2}\sin\dfrac{2\pi x}{c} + \dfrac{1}{3}\sin\dfrac{3\pi x}{c} - \ldots\right)$.

Platform scales are best suited for most weighing operations. This type is quite sensitive when new, but its original sensitiveness is soon lost if the knife-edges are allowed to become rusty from exposure to dampness or become dulled from careless and excessive loading. All scales should be tested with standard weights and adjusted whenever used in important work. **Spring and torsion balances** are usually not very reliable and are used chiefly because they are easily portable and compact. Zero reading is not dependable. Careful calibrations are essential. **Automatic indicating scales**, particularly of the pendulum ("Toledo") type, are the best for many purposes such as weighing the fuel consumption of oil engines. A pointer on a dial indicates the weight continuously. Automatic scales operating with a spring mechanism are subject to the same faults as the usual types of spring balances. **Automatic scales** for coal bunkers are filled under the chute from the bunker till a predetermined weight has accumulated. The supply is then shut off, and the scoop trips and discharges. Such devices are usually integrating, and automatic scales for weighing fuel being conveyed to power houses and furnaces are recording.

MEASUREMENT OF AREAS

The areas of irregular figures such as indicator diagrams are generally determined either by measuring the lengths of ordinates drawn on the figure and inserting their values in certain formulas or "rules," or from readings of planimeters.

In the **ordinate method**, the figure (Fig. 11) is divided by parallel lines into an even number of strips of equal width w and the ordinates $y_0, y_1, y_2 \dots y_n$ measured. Letting n = number of strips (the greater the value of n, the greater the accuracy of the method), the area A may be approximately determined by using one of the following formulas:

FIG. 11.

1. **Trapezoid rule:**

$$A = w(\tfrac{1}{2}y_0 + y_1 + y_2 + \cdots y_{n-1} + \tfrac{1}{2}y_n)$$

2. **Durand's rule:**

$$A = w(0.4y_0 + 1.1y_1 + y_2 + y_3 + \cdots y_{n-2} + 1.1y_{n-1} + 0.4y_n)$$

3. **Simpson's rule** (see also p. 106):

$$A = \tfrac{1}{3}w(y_0 + 4y_1 + 2y_2 + 4y_3 + \cdots + 2y_{n-2} + 4y_{n-1} + y_n)$$

The various lengths required by the foregoing methods can be conveniently added by laying them off with dividers one after the other along a straight line and finally measuring the total length of the line.

Planimeters are instruments for measuring areas. The **Amsler polar planimeter** (Fig. 12) consists of two arms pivoted at O. At the end of one arm is a tracing point T, and at the end of the other a "fixed point" P. Attached to the tracing arm is a small graduated wheel W. In using the instrument, mark a starting point for the tracing point T on the contour of the figure to be measured and observe the reading of the graduated wheel W. If the figure is traced in a **clockwise** direction, back to the starting point, the area measured is found by subtracting the first reading from the last; but if the tracing point is moved around in a counterclockwise direction, the last reading must be subtracted from the first. The foregoing applies to small areas of only a few square inches, such as indicator cards, etc. For large figures, the area of the zero circle of the instrument enters into the

any form of tapered or rounded open-end tube will give accurate impact pressures, but it is always a question whether the static pressure measured is the true static pressure at the opening of the impact tube. Nevertheless when the Pitot tube is accurately positioned parallel to the axis of a continuous pipe, using straightening vanes and several diameters (5 to 20) of straight-pipe approach, the accuracy of the individual velocity readings is probably well within ±1 percent. Accurate calibrated manometers must be used. For obtaining the average velocity across the pipe, a traverse is necessary, and in a round pipe this is usually made on each of two diameters, with positions in the center of area of three or more concentric areas (preferably five or more, see Table 11), depending on the pipe size and the required accuracy (see Cole and Cole, "Pitot Tubes in Large Pipes," and Hubbard, "Investigation of Errors of Pitot Tubes," *Trans. A.S.M.E.*, Aug., 1939). For rectangular ducts, the readings are taken in the center of equal rectangular areas, using 16 to 64 areas, depending on the duct size. Pitot tubes have been designed which deviate greatly from the form shown in Fig. 22, using static openings facing downstream (see p. 279) or at an angle with the stream. Calibrations of such Pitot tubes are necessary. If a Pitot tube is preceded by a long run of straight pipe, approximate results may be obtained by fixing the tube in the center of the pipe and using a factor to obtain the average velocity. For turbulent flow, this factor (ratio of true average velocity to center velocity) varies within the range of about 0.77 to 0.92, being lower for rough pipes than for smooth ones. If this method is to be used, it is advisable to make a special determination of the factor. For the case of laminar flow, the factor is about 0.5. The impact tube is sometimes used separately, either with a static connection in the side wall of the pipe or in open streams where the static pressure is atmospheric. As long as the plane of the impact opening is normal to the flow, the size, shape, and wall thickness of the impact tube can be varied widely without affecting the accuracy, but the diameter of the tube should not be over 5 percent of the diameter of the air stream.

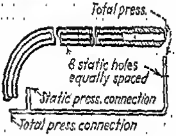

FIG. 22.—Standard Pitot Tube for Fan Testing (A.S.M.E. and A.S.H.V.E. Test Codes).

Table 11. Layout Measurements for Pitot-tube Traverses

Number of equal areas	Total number of readings	Distances from center of pipe to point of reading in percent of pipe diameter					
3	12	20.4	35.3	45.5			
4	16	17.7	30.5	39.4	46.6		
5	20	15.5	27.2	35.3	41.7	47.4	
6	24	14.5	25.0	32.3	38.2	43.3	47.9

MEASUREMENT OF POWER

Dynamometers, or instruments for measuring force or "power," are in general of two kinds: (1) those **absorbing** the power by friction and dissipating it as heat; (2) those **transmitting** or passing on the power they

calculation of areas. This correction has to be added whenever the fixed point is inside the area which is being measured. Its value can be determined by measuring a circle or other figure of known area. The difference between the known area and that recorded by the instrument is the area of the zero circle. The area of the zero circle is stamped conspicuously on many planimeters. For measuring figures of indefinite length and limited breadth, **roller planimeters** must be used. They are expensive and are not much used in America. Special planimeters are available (Coffin "averager") for determining directly the mean height of an indicator card.

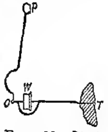

FIG. 12.—Planimeter.

Integrators for Circular Charts. Instruments have been developed for measuring the mean ordinate of circular charts having a constant radial scale. Such instruments are made by the Bailey Meter Co., Builders Iron Foundry, The Foxboro Co., Keuffel & Esser Co., and others.

For detailed information on the theory and operation of both polar and radial planimeters, see A.S.M.E. Power Test Codes, Instruments and Apparatus, Part 15, "Measurement of Surface Areas."

FLUID METERS

REFERENCES: Reports of the A.S.M.E. Research Committee on Fluid Meters: Part 1, "Theory and Application"; Part 2, "Description of Meters"; Part 3, "Selection and Installation." A.S.M.E. Power Test Codes, Instruments and Apparatus, Part 5, "Measurement of Quantity of Materials." Stewart and Doolittle, "Fluid Flow Measurement," *Instruments*, July, 1939, pp. 175–198. Report of the A.G.A.-A.S.M.E. Orifice Coefficient Committee (published by the A.S.M.E., 1935).

Selection of a meter for a given application depends on the rate of flow, the fluid to be metered, and the accuracy required (see Table 9). Quantity meters are usually more accurate than rate meters, especially for the lower rates of flow and for non-steady conditions. For large quantities and when the flow is free from sudden variations, the rate meters are accurate and are less expensive. They are also well adapted to combinations for indicating, recording, and totalizing the flow rate. Special selections are necessary for viscous liquids, for liquids containing sediment, or for gases or vapors with entrained particles of solids or liquids. Most commercial meters are designed for metering a specified fluid.

Gas and Air Meters

Bellows gas meters are generally used in connection with the sale of fuel gases, but they are also suited to other measurements of clean gases or air in the temperature range from 32 to 110 F. Such meters consist of a casing divided into two chambers by a vertical partition. Within each chamber is a measuring receiver in the form of a leather-walled diaphragm. Slide valves admit gas alternately into the flexible measuring receivers, and the reciprocating movements of filling and emptying actuate a set of counter dials. Connections are such that the movement of one bellows is at mid-position when the other is passing the end or dead point. Bellows meters are rated at a pressure drop of 0.5 in. of water and are usually adjusted to within ± 1 percent error, though the error may increase with use and be larger at the greater rates of flow. These meters are well suited for intermittent duty, and their accuracy is almost unaffected by variations in the

measure and wasting only a small part in friction. Devices for measuring power may be classified for convenience as follows:

Type	Approx limit of speed, rpm	Usual power limit, hp	Probable error, percent
Prony brakes:			
Block	2,000	10	1–5
Band	1,000	5	1
Wooden cleats on bands	1,000	200	½–1
Rope (¾-in.) with wooden cleats	1,000	50	1
Fluid friction dynamometers:			
Froude (ordinary "water" brake)	10,000	25,000	⅕–½
Westinghouse (turbine)	4,000	5,000	$\frac{1}{10}$–⅕
Alden	1,000	5,000	½–1
Fan brake	2,000	200	1–5
Electric dynamometers:			
Electric eddy-current brake	6,000	300	⅕–¼
Electric generator	750–4,000	30,000	$\frac{1}{10}$–⅕
Transmission dynamometers:			
Torsion	1,000–3,000	50,000	1–5
Kenerson	1,500	100	2

The speed limits given above are approximately the highest allowable. Limits of horsepower refer to the largest sizes made commercially. Any of these types (with the exception of the Westinghouse turbine) are made in sizes to absorb from 1 hp up. The probable error stated is very approximate and refers to the apparatus in fair adjustment.

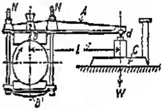

Fig. 23.

Absorption Dynamometers

A Prony brake consists of a lever A (Fig. 23) and blocks B, B' supported on a revolving drum or pulley. The blocks are held in place and tightened by the thumb nuts N, N. The tendency of the arm A to revolve is prevented by the resistance of a platform scales C, as shown, or by weights attached. If the pressure on the pedestal at d due to its own weight and that of the lever arm A is W_0 lb (determined by the weight on the scales when the brake block is supported at B on a three-cornered prism or on a small rod of circular section), the gross weight at the end of the brake arm with load is W lb, the length of the brake arm in feet is l, and the number of revolutions per minute is n, then brake horsepower $= 2\pi ln(W - W_0)/33{,}000$.

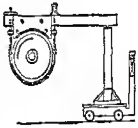

Fig. 24.

The disadvantages of any form of Prony brake are that they require continued adjustment for constant power and that water cooling is necessary for moderate and large powers, with consequent untidy conditions.

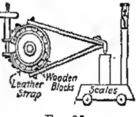

Fig. 25.

Figs. 23–25.—Types of Prony Brakes.

According to Bach, suitable dimensions for a brake of this type are given by the formula $bd =$ bhp $\times 12/k$, where d is the diameter of the brake pulley, in.; b the breadth of the brake blocks, in. (usually about 1.5 times the diam of the shaft); and k = ½

flow rate. They may be obtained with sheet-metal casings for low pressures and with cast iron casings for high-pressure lines.

Table 9. Classification of Fluid Meters

Common name or type	Fluids metered	Class of measurement	Maximum capacities	Accuracy ± %
Quantity meters:				
Weighers and tilting traps	Liquids	Weight	Unlimited	1
Disk water meters	Clean liquids	Volume	20–1,000 gpm	2–4
Piston meters	Clean liquids	Volume	1–1,000 gpm	0.5–2
Drum condensate meters.	Hot water	Volume	250–12,000 lb per hr	2–3
Bellows gas meters	Gases	Volume	150–17,000 cfh	1–3
Wet gas meters	Gases	Volume	100–100,000 cfh	0.5–2
Rotary gas meters	Gases	Volume	500–1,000,000 cfh	0.5–2
Rate meters (for steady flow only):				
Orifice plate	Any fluid	Head (constant area)	Unlimited	1–3
Flow nozzle	Any fluid	Head	Unlimited	1–3
Venturi meter	Any fluid	Head	Unlimited	1–3
Pitot tubes	Any clean fluid	Head	Unlimited	1–3
Weirs	Liquids (in open channels)	Head area	Unlimited	0.5–2
Area meters (variable orifice).	Clean fluids	Area (constant head)	Unlimited	1–3
Velocity meters	Air or water	Velocity	Unlimited	2–10
Thermal meters	Air and clean gases	Weight	25,000–2,000,000 cfh	1–2

Wet gas meters are usually of the revolving-drum type, sealed with water, but they may also be oil sealed and may employ a nutating bell instead of a revolving drum. With careful adjustment of the liquid level, the accuracy of laboratory-size wet meters with large dials may be well within ±1 percent. These meters should not be subjected to severe pulsations or rapid fluctuations of the flow rate, and the gas should be free from dust or corrosive constituents. Integrating registers of the multiple-clock-dial type are normally mounted in the meter case. Rotating-drum meters are suited for low pressures only.

Rotary dry-gas meters are adapted for very wide ranges of operating temperature and pressure and for high rates of flow. They are unaffected by pulsating or intermittent flow, will handle foul gases as well as clean gases, and operate on a pressure drop of 0.1 to 2.0 in. of water. These meters can register flow in either direction, but it is better to install them with the gas entering from the top to eliminate dirt settlement in the meter casing. Normal capacities vary from 500 to 1 million cu ft per hr, but larger meters can be furnished. These meters can be adjusted to have an error within 0.5 per cent, but an exact calibration is difficult.

Orifice, nozzle, Venturi, and Pitot meters for gas and air are widely used, especially for measuring high rates of flow (see Head Meters, pp. 1802 to 1807).

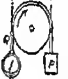
Thermal meters depend on observations of the change of temperature of gas or air when a known amount of heat is added. Electric thermal

for cooling air and varies from 2.5 to 5 for water cooling as the speed increases. F. A. Halsey (*Am. Machinist*, Apr. 4, 1912) states that the brake-drum surface for a water-cooled Prony brake should not be less than 0.09 sq ft per bhp, to avoid the danger of the blocks taking fire.

In Fig. 24, the lower block in the preceding figure is replaced by two steel bands and narrow cleats of maple or oak attached by wood screws inserted from the outside through the bands; the upper block is lined with similar cleats, the screws being countersunk. At least ½ in. spaces should be allowed between cleats for air circulation. In all such constructions for dynamometers, screws and nails should not touch the friction surface, as they are likely to cause the friction to be variable and the sound production is objectionable. Grooves may be cut in the inside surface of a few of the cleats and these grooves filled with grease to provide a little lubrication. A similar brake is shown in Fig. 25, where maple cleats are screwed to a leather belt. This type is more easily adjustable to different sizes of pulleys than the preceding designs, but it is not so durable. Washers should be placed on the heads of the screws fastening the cleats to the belt. If a brake wheel similar to Fig. 26 is used so that it can be satisfactorily cooled with water on its inside surface, the cleats should provide 5 to 10 sq in. of friction surface per bhp according as the speed ranges from low to high.

Fig. 26.

Band and rope brakes are also frequently used. The simplest form is shown in Fig. 27. If Q is the reading of the spring balance, lb; r the wheel radius, ft; P the applied weight, lb (both P and Q must be net); and n the rpm, then $\text{bhp} = 2\pi rn(Q - P)/33{,}000$. This type of brake is very accurate and sensitive, but it is suitable only for low powers. About the same friction surface must be allowed as given for wooden blocks by Bach's formula (see Prony Brakes, *ante*). A convenient type of **rope brake** with "stay" cleats is shown in Fig. 28, the rope being passed around the circumference of the pulley. In this arrangement, the cord or rope supporting the spring balance must have some point of attachment overhead. It is advisable to provide an anchoring rope or wire securely attached to the weights P, and its weight (or that part of it suspended) must then be added to P. Similarly, the weight of the rope between the spring balance and the point where it touches the pulley should be deducted from the readings of the spring balance. Usually four to six cleats are used on rope brakes. These cleats are often attached to the ropes by strong copper wire passed through a strand of the rope and over the backs of the cleats. The best arrangement is to place the



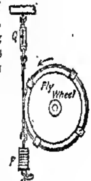


Fig. 27. Fig. 28.
Rope Brakes.

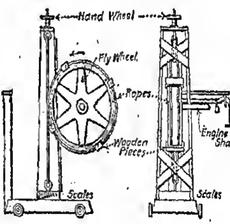

Fig. 29.—Rope Brake.

meters are made by Cutler-Hammer Inc., Milwaukee, and consist of an electric heater, two electric resistance thermometers, and a current regulator (Fig. 13). The current regulator automatically maintains 2 deg F difference between entrance and exit of the meter; hence wattmeters and watt-hour meters may be used to read flow directly. Capacities are 25,000 to 2 million cu ft per hour.

Area meters for gas and air are of two types, the variable-orifice and the multiple-orifice meters. Figure 14 is a diagram of a typical variable-orifice area meter. The Ingersoll-Rand and the Rotameter (Fischer and Porter Co.) are of the variable-orifice type, operating on a constant differential head as determined by the weight of the movable unit. These meters are self-adjusting for wide variations in the flow rate. The Toolometer (New Jersey Meter Co.) is a similar meter using multiple orifices instead of a single variable opening. Several manufacturers offer gate-type variable orifices or multiple-orifice units which are intended for manual adjustment. Since area meters are essentially orifice meters, they are subject to the advantages and disadvantages of orifice metering, but they have a much wider range of capacities. Their accuracy is usually within ± 2 percent.

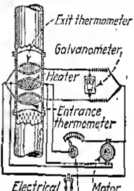

FIG. 13.—Electric-thermal Gas Meter.

Velocity meters of the open type are widely used for measuring air velocities and quantities, and these instruments are called anemometers. There are two types of anemometers, the mechanical and the thermal.

Rotating-vane anemometers usually have four to eight flat vanes mounted on a wheel, though a single propeller-shaped blade is sometimes used for high-speed work. The wheel is connected to a counting train, and the dials are calibrated to read directly in feet. A lever for setting all dials to zero may be included. The total dial reading for a timed run divided by the total elapsed time in minutes gives the air velocity in feet per minute. This type of instrument is especially suited for obtaining the average air velocity over a large area, as for instance in the stream from a fan or from an air-conditioning grille. The procedure is then to subdivide the area into small areas about the size of the instrument to be used and to hold the instrument successively in each small area for a short peroid (10 to 30 sec), stopping it only after all areas have been covered. If the volume of air is required, the average velocity is multiplied by the area. This result is an approximation unless the anemometer has been calibrated for the specific conditions of use. A rotating-vane anemometer should not be held in the hand during operation, but mounted at the end of a thin handle.

FIG. 14.—Orifice-and-plug Steam Meter.

The **rotating-cup anemometer** is used principally for meteorological observations. The standard Weather Bureau anemometer has three cups, with the arms set at 120 deg. In addition to the indicating dial on the instrument, reading in miles, the instrument may be equipped with electrical contacts to operate a counter every ½ mile, or the unit may contain an electric generator from which both indicating and recording instruments are energized.

rope on the wheel double. In Fig. 29, an arrangement is shown in which both ends of the rope are attached to a rigid frame supported on weighing scales. The reading of the scales (corrected for the weight of the frame) gives $Q - P$ directly. A double rope ¾ in. diam with six cleats each of about 12 sq in. on the "friction" side will absorb 50 bhp. For engines of smaller power, ½ in. rope with four cleats is used. By steeping the rope in a mixture of melted tallow and graphite, the frictional properties are improved. Manila or cotton ropes are used.

The water brake is a fluid-friction dynamometer somewhat similar in construction to a centrifugal pump. The dynamometer casing is supported on antifriction bearings and tends to revolve with the rotor. An attached brake arm, supported on scales, measures the turning moment, and the horsepower absorbed is calculated in the same way as for a Prony brake. One or more smooth rotors may be used in a water brake, or additional friction may be obtained by vanes and recesses on casing and rotor. The horsepower absorbed by a water brake varies approximately as the cube of the rpm and as the fifth power of the rotor diameter (see Culver, "Investigation of a Simple Form of Hydraulic Dynamometer," *Mech. Eng.*, Oct. 1937). Several commercial models of water brakes are available (Taylor Mfg. Corp., C. H. Wheeler Mfg. Co., Murray Iron Works, Bendix Products Corp., etc.). A water brake is sometimes mounted on the same shaft with an electric dynamometer to produce a dynamometer unit of sufficient capacity and flexibility to test large automotive and airplane engines.

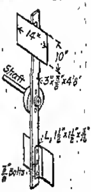

Fig. 30.—Fan Brake Dynamometer.

For the approximate determination of the horsepower of high-speed engines, a **fan brake dynamometer** consisting of two fan plates (Fig. 30) to be attached to the shaft is very convenient but is less reliable than any of the other methods described. The power is absorbed by the "fan" action of the plates on the surrounding air, which depends on the size of the plates, their distance from the center of rotation, and upon the cube of the rpm. Figure 31 shows curves for determining the bhp for varying speeds of a fan with rectangular blades 10 in. wide in a radial direction, 14 in. wide axially, and ½ in. thick. These curves are for atmospheric pressure and a temperature of 70 F. Errors are introduced by other pressures, temperatures, and the location of near-by objects. The numbers on the curves indicate inches from the center of one plate to the center of the other. This distance is varied by shifting the bolts. Ordinary weather changes may affect the power absorbed by a fan dynamometer by as much as 20 percent. It is convenient for comparative factory tests (see Merriam and Staples, "Aerodynamic Dynamometer," *Mech. Eng.*, July, 1938).

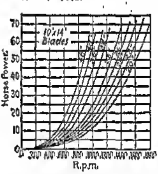

Fig. 31.—Power Absorbed by Fan Brake Dynamometer.

Electric dynamometers include calibrated generators, calibrated motors, cradle-mounted generators and motors, and magnetic-drag or eddy-current brakes. The calibration of an electric generator or an electric motor con-

Bridled-vane anemometers are direct-reading velocity meters consisting of one or more vanes, the movement of which is resisted by a calibrated spring. When the air velocity produces an impact force tending to move the vane, this force is resisted by the spring, and the equilibrium position of the vane indicates the air velocity. The range of the instrument may be changed by varying the size of the air openings and its versatility increased by using various types of impact fittings or jets at the end of a rubber connecting tube as in the case of the Velometer (Ill. Testing Laboratories).

The **heated-thermometer anemometer** is an ordinary thermometer with an electric resistance coil wound on the bulb (see "The Heated Thermometer Anemometer, C. P. Yaglou, *Jour. Ind. Hyg. Toxol.*, Oct., 1938, p. 497). By impressing a constant voltage across the coil and comparing the reading of this thermometer in the air stream with that of an unheated thermometer in the same stream, a difference is obtained which is a function of the air velocity. The range of the instrument is changed by changing the impressed voltage. After suitable calibration, an extreme range of air speeds from the minimum natural convection currents in a room to a mile-a-minute stream may be measured with the same instrument. The **heated-thermocouple anemometer** operates in a similar manner and has the additional advantage of being distant reading.

Calibrations of anemometers are made either by moving the instrument in still air or by mounting the instrument in a wind tunnel and comparing its readings with those of some other air meter. The still-air calibration is usually made with the instrument mounted at the end of a rotating arm, and for accuracy within 3 percent an arm at least 10 ft long should be used. Calibrations can also be made in the discharge of a large rounded-entrance nozzle, but they must not be attempted in the stream from an ordinary duct or from an orifice.

Steam meters are usually some form of head meter, such as the orifice, nozzle, or pitot tube (see Head Meters, pp. 1802 to 1807). The St. John steam flow meter (American District Steam Co.) is an area meter of the orifice-and-plug type, equipped with a direct pointer indicator and a strip-chart recorder (Fig. 14).

Liquid Meters

Rotary-disk meters are generally used for metering cold water on domestic and commercial service lines. They consist of a circular metering chamber, with a conical roof and floor (Fig. 15) divided into two equal compartments by a "nutating" disk. The disk does not rotate about its own axis, but the shaft on which it is mounted generates a cone with apex downward. Motion of the disk is guided by the two half-balls mounted upon it, and with each complete revolution a fixed volume of water passes through. The circular motion of the upper end of the disk shaft operates the counting gears. Disks are usually made of hard rubber molded over metal reinforcement. "Frost-proof" disk meters have a breakable bottom plate and a separable metering chamber. Standard sizes of disk meters are for ½ to 6 in. pipe line connections, with "normal" capacities from about 20 to 1,000 gpm. The error of a disk meter will usually be 2 or 3 percent, and they are intended for use only for clean water below 125 F, though they are also furnished with metal or with carbon disks for hot water and other clean liquids.

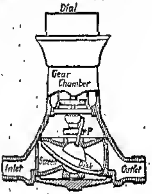

Fig. 15.—Rotary-disk Water Meter.

Piston meters are made in a variety of combinations of one, two, or more pistons, reciprocating or oscillating in fixed chambers. A typical piston

sists in determining the efficiency of the machine over a range of operating conditions. For convenience and for accuracy in interpolation, an input-output curve should be drawn. With the aid of this curve, the machine may then be used as a dynamometer over that range of operating conditions covered by the calibration, by measuring the electric power only.

The **electric-cradle dynamometer** (Fig. 32) is an electric motor or generator with rotor and stator mounted in concentric ball bearings, so that the stator is free to turn. The torque can then be measured by suitable scales. A separately excited d-c machine is usually used and can be used over a wide range of operating conditions both as a motor and as a generator.

Magnetic drag or eddy-current brakes are similar to cradle-mounted generators, but the electrical energy is dissipated within the machine itself. Load rheostats are therefore not necessary, and the entire installation is more compact and less expensive than that of a cradle-mounted d-c machine, but of course the motoring feature cannot be obtained in a magnetic brake. Commercial water-cooled magnetic brakes are available for automotive engine testing (Mid-West Dynamometer and Engineering Co., Electric Products Co., etc.).

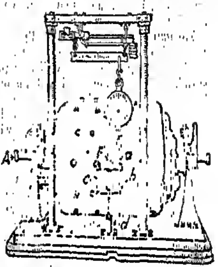

FIG. 32.—Electric-cradle Dynamometer.

A **chassis dynamometer** is an assembly that includes treadwheels and an absorption brake, so mounted that an automobile or a motor truck may be tested as a complete unit. The rear wheels of the automotive vehicle revolve upon the treadwheels of the dynamometer. Chassis dynamometers are made either with a ramp for floor mounting, or they may be located in a pit with the treadwheels at floor level and the controls at a convenient operating height. Several sizes are available, with capacities up to 400 hp and 100 mph (Bendix Products Corp.).

Airplane engines are often tested by being set up on a **torque stand** with a cradle attachment. The testing is done with the propeller attached. The engine is supported on ball or roller bearings in such manner that it is free to rotate, about the crankshaft as an axis, through a small angle. The torque required to prevent such rotation is measured.

Transmission Dynamometers

Torsion Dynamometers. When a shaft is subjected to a twisting moment, an angular twist is produced which is proportional to that moment. Thus, if the angle of twist is produced by a twisting moment T in in-lb and n is the rpm, then bhp $= 2\pi Tn/(12 \times 33{,}000)$.

Torsion meters, although applicable to large as well as small powers, have their most important applications for measuring shaft horsepower of marine turbines and engines. Several installations have been made of a torsion meter in which the angle of twist of the power-transmitting shaft is measured by the electric-gage principle. This gage uses reactance coils and a bridge circuit (see Hathaway and Lee, "The Electric Gage," *Mech. Eng.*, Sept., 1937).

meter for water is the Worthington meter (Fig. 16). Water is admitted alternately at the two ends by a slide valve moving on seats in a bottom plate containing the inlet and discharge ports. Piston meters are capable of a high degree of accuracy, but actual errors will depend on the type of service for which they are designed, on maintenance, and on the accuracy of adjustment.

Revolving drum condensate meters are common for metering purchased steam, and they usually operate at or near atmospheric pressure, with gravity discharge. The principle of operation is shown in Fig. 17. Standard registration for these meters is integration only but some of the larger sizes may be equipped with circular chart recorders. Sizes range from 250 to 12,000 lb per hour. An error of 2 or 3 percent may be expected. Approximately 18 in. static head is required to operate the meter, and the meter must be installed so as to be self-clearing or accuracy will be affected. Ordinary pulsations or intermittent flow will not affect the accuracy of the revolving drum meter.

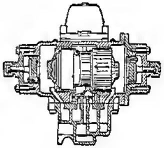

FIG. 16.—Worthington Piston Water Meter.

Rotary-displacement meters of the lobed impeller, gear, or screw type are sometimes used for water, though they are better adapted to oil and other lubricating liquids.

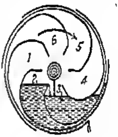

FIG. 17.—Condensate Meter.

Velocity meters for water are of two types: the **current meter** for measuring the velocity in open channels (see p. 278), and the enclosed **propeller or turbine type.** Enclosed velocity meters are made in a variety of designs and in sizes from ¾ to 12 in. pipe. The smaller meters are used chiefly for hot water or for dirty water. The large meters are suitable for high rates of flow only, and if accuracy at all rates is necessary, a **compound meter** consisting of both velocity meter and disk meter, with suitable automatic valves, is often installed.

Weir Meters. The weir is an open-channel or tank meter in which the registering device is operated by a change in height of the surface of the liquid (see pp. 259 to 263). In most mechanical engineering applications, the V notch or triangular weir is preferred because of its great capacity range (about 20 to 1). The 90 deg V notch is the most common, the 60 deg is sometimes used, and the "half-notch" (53 deg 8 min) and the "quarter-notch" (27 deg) have the advantage of even fractional capacities with the same meter register. Accuracy should be within 2 percent, and in some cases may be within 0.5 percent. Standard maximum heads for commercial meters are usually 4 to 15 in., though larger meters can be obtained (up to 4 million lb per hr). Secondary devices of most commercial meters are actuated by floats; indicators, recorders, and integrators are available. To obtain charts and scales with equal divisions or increments, special shapes of floats, cams, or tanks are used.

Head Meters

A head meter consists of two units, a primary device that produces a "differential head" or pressure difference, which varies as the square of the

For descriptions of various types of transmission dynamometers, see Diederichs and Andrae, "Experimental Mechanical Engineering."

Engine Indicators

Essential requirements for a good indicator are (1) a calibrated spring with a minimum of inertia and a high natural period of vibration; (2) a lightweight well-fitting lubricated piston; and (3) a light sturdy rod and linkage mechanism between piston and tracing point. For an exhaustive study of the development and use of indicators of all types, see De Juhasz, "The Engine Indicator," *Instruments*, June, 1932, to July, 1933 (14 chapters). Indicators are usually made in three sizes, giving cards approximately 5 × 2¾, 3½ × 2, and 2¼ × 1¼ in., and used, respectively, for low-, intermediate-, and high-speed work.

Indicator springs are usually double-coil spiral springs, calibrated in terms of the pressure required at the piston to produce a movement of 1 in. at the marking point. An indicator piston of ½ sq in. area is the normal or standard size. When used with pistons of other areas, the spring scale will be inversely as the piston area. *Indicator springs should be calibrated in place by the dead-weight test method.* This also furnishes a check on the pencil motion or magnifying gear, which should be free from lost motion as the pressure is increased and decreased. **Outside-spring indicators** are preferable for greater convenience in handling and because the spring is not subjected to considerable temperature changes. The indicator piston requires lubrication; for internal-combustion-engine service, a built-in lubricating arrangement, such as a grease feed, is desirable.

The paper drum is of light construction for minimum inertia, with an internal helical spring easily adjustable for tension. Indicators are available for recording numerous diagrams on a continuous strip of paper fed from a spool. In some cases, provisions may be made for driving the drum at uniform speed, for a pressure-time record. Special non-stretching **indicator cord** should be used. Stretch of the cord should be less than ½ percent with a 10 lb pull; a wire core will reduce the stretch by 50 percent. Indicator cord should be as short as possible, long connections being made by rigid links, wire or steel tape with slack take-up. **Integrating indicators** are available, using either mechanical or electrical integrators.

Precautions in the Use of Indicators. Unless an engine indicator is carefully handled, the diagrams taken with it may be in error from 5 to 10 percent. The following are the most important considerations:

1. Springs must be calibrated frequently.
2. The tension of the spring in the drum should be adjusted.
3. Before an indicator is used, all working parts should be cleaned and oiled. The piston and its rod should be examined before attaching the spring to determine by lifting the pencil lever and letting it fall whether these parts move easily. Attach the spring firmly, and observe carefully that there is no lost motion. This precaution is most important in indicators having a bead on the spring for making a ball-and-socket joint. To put this kind of spring in place properly, the piston rod should be screwed tightly into the piston when the lower adjusting nut is loose. Then screw up this nut just tight enough to permit a slight movement. If the nut in the piston has been properly adjusted, there should be no lost motion between the rod and the piston, and still there should be flexibility in this joint permitting the piston to adjust itself in the indicator cylinder.
4. Oil the piston with cylinder oil every time it is taken from the cylinder. Many careful engineers oil the piston regularly after taking about ten diagrams. A new piston usually requires more lubrication than one that is well worn.

rate of flow, and a secondary device, usually a manometer of some kind for measuring the differential head (see Pressure Measurements, p. 1792). The common head meters are (1) thin-plate sharp-edged orifice; (2) flow-nozzle or rounded-entrance nozzle; (3) Venturi tube; and (4) Pitot tube (or impact) tube). Selection of one of these four depends on requirements. **Pressure loss** caused by the *Pitot* tube is zero; for the other three devices, a loss of 10 to 90 percent of the differential pressure will occur. **Accuracy** of all four types of head meters should be within 2 percent if they are properly installed and operated. Head meters can be constructed for almost any desired capacity, and they may be used for any reasonably clean fluid with steady non-pulsating flow. Discharge coefficients are only slightly affected by the fluid used. Variations due to meter size, properties of the fluid metered, and rate of flow are all taken into account by stating orifice coefficients as a function of the dimensionless Reynolds number $DV\rho/\mu$ (see pp. 250 and 288). The Pitot tube is usually used with an indicating manometer only, but the other head meters are available with a wide variety of integrating and recording as well as indicating devices, both for near and distant reading.

Meter location is very important in the case of head meters, as upstream disturbances affect the flow. Various codes and instructions specify 5 to 40 diam of straight pipe upstream, depending on the diameter ratio and the fittings in the line. It is good general practice to allow 10 diam upstream and 5 diam downstream, if possible, and to use straighteners (egg crate or nest of tubes) several diameters upstream from the meter.

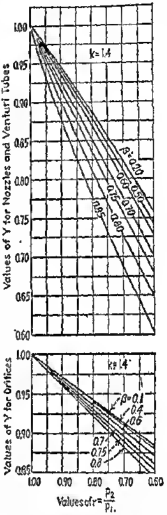

Fig. 18.—Values of the Expansion Factor Y (β = Ratio of Orifice or Throat Diameter to Pipe Diameter).

The flow equation for any head meter measuring a liquid, or measuring a compressible fluid with a differential head less than 40 percent of the upstream absolute pressure, is

$$Q = YMCA\sqrt{2gh} \qquad (1)$$

where Q = volume rate of flow, cu ft per sec (multiply by 60 for cfm); Y = compressibility factor or expansion factor (see Fig. 18); M = velocity of approach factor or "meter constant," the same for orifices, nozzles, and Venturi meters (see Table 10); C = coefficient of discharge, for values see discussion of each type of meter; A = measured area of minimum section of the throat, tube, or orifice, sq ft; g = acceleration of gravity = 32.174; and h = differential head in feet of the fluid flowing (conditions as of the upstream tap).

For large departures from atmospheric temperature, an additional correction for thermal expansion of the opening should be applied (about +0.5 percent for 400 F; see Fluid Meters, Part 1, Fig. 55). For derivations of

5. Adjust the handle on the pencil motion so that when the pencil is sharp it will draw a very fine line. If the pencil presses heavily on the paper, friction and shifting of the paper may distort the diagrams. Prepared metallic paper if used with blunt brass points increases pencil friction considerably above what it is when sharp lead pencils or ordinary "household" pins are used.

6. Adjust the length of the indicator cord, and turn over the engine by hand to make sure the cord is of proper length.

7. Immediately after a diagram has been taken, it should be examined and any irregularities or faults noted and corrected.

8. Mark diagrams plainly as regards head and crank ends of double-acting engines, the time, scale of spring, and name or initials of the person taking them.

9. Best results are always obtained with an indicator at each end of the cylinder of a double-acting engine. Tests show that sharp bends, long pipes, and restrictions of bore may cause errors in indicator diagrams as great as 20 percent (W. F. M. Goss, *Trans. A.S.M.E.*, 1896). This is a particularly important consideration in air and ammonia compressors having very small clearance and in long-stroke engines where the piping for a three-way cock for a single indicator would add considerably to the clearance.

10. The indicator cock should be kept closed, and the cord to the reducing motion should be unhooked except when a diagram is being taken.

High-speed operation introduces problems due to inertia and vibration. Mechanical indicators of the high-speed type embody stiff springs, light-weight parts, large pistons, and magnification of about 8 times between piston and pencil point. One successful model uses a cantilever spring (Fig. 33). Very small diagrams are also drawn by high-speed *indicators* (*¾ × 2 in.* or *smaller*). Stiff springs and light moving parts increase the natural frequency of vibration of the assembly. The spring mechanism should have a natural frequency of at least 10 to 12 oscillations per stroke of the engine.

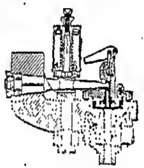

FIG. 33.—High-speed Indicator with Cantilever Spring.

For high-speed-engine research on internal-combustion engines, there are several modifications of the mechanical high-speed indicator. **Micro-indicators** trace very small diagrams which must be greatly magnified for analysis. **Optical indicators** obtain magnification by optical systems and record photographically. There are many well-developed optical indicators of which a number such as the Manograph, the Hopkinson, the Midgley, and the von Gehlen have been produced commercially. Optical indicators have a piston or a diaphragm in the pressure chamber, operating against a beam spring and transmitting a very small motion to a mirror which reflects light from a point source. A motion is imparted to the mirror in another plane (or to a second mirror in the system) by some type of connection to the engine piston or shaft. The card drawn by the light beam is magnified by the optical arrangement and can be either viewed on a ground glass screen or photographed.

In the **electrical indicator**, the characteristics of an electric circuit are made to change by the changes in pressure in the cylinder. The recording element is usually an oscillograph. The resistance, capacity, impedance, or potential in the electrical circuit may be varied by the pressure element. A carbon-pile rheostat suitable for the resistance method was developed at the Bureau of Standards (see *Tech. Paper* 240; also Martin and Caris, *Jour. S.A.E.*, July, 1928). The electrical-potential method differs from other indicator devices in that it utilizes a piezoelectric crystal instead of an indicator spring as a pressure-responsive element. With a vacuum-tube amplifier

Table 10. Velocity of Approach Factor M

For orifices, nozzles, and venturi tubes

flow equations and for equations applying to flow through orifices and nozzles with greater pressure drop, see pp. 253 to 259, and 353 to 358.

Thin-plate orifice meters are the most common head meters because they are relatively inexpensive, easy to construct and easy to install, and more data are available on the orifice than on any other metering device. A thin-plate concentric orifice is a flat diaphragm with a circular hole in the center. It may be clamped concentrically between the flanges in a pipe line, at the

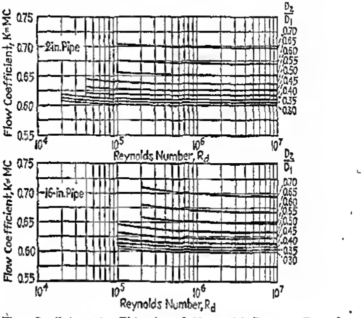

FIG. 19.—Flow Coefficients for Thin-plate Orifices with Pressure Taps One Diameter Upstream and One-half Diameter Downstream.

intake or the discharge end of a pipe or duct, or in the wall of a plenum chamber or a suction box. The hole must have a 90 deg corner at its upstream face, with no burrs or rounding, and the cylindrical edge should not exceed 5 percent of the orifice diameter. When thicker plates are used, the downstream corner may be beveled at 45 deg. Plates must be flat, strong enough to resist bulging, and non-corroding. **Pressure connections** recognized by the A.S.M.E. Code are as follows: (1) **flange taps**, with the centers of the holes 1 in. from the respective faces of the orifice plate; (2) **vena contracta taps** with the upstream hole located one pipe diameter from the upstream face and the downstream hole at the vena contracta; (3) **radius taps** with the upstream hole located one pipe diameter from the upstream face and the downstream hole one-half diameter from the downstream face. Drill size for the pressure hole at the inner surface of the pipe should not be over ¼ in. for 3 in. pipe or smaller, or over ½ in. in any case. The inner surface around the pressure hole should be smoothed with emery cloth. **Coefficient**

and a cathode-ray oscillograph, synchronized pressure-time curves may be obtained (R.C.A. Mfg. Co.). Electrical indicators have the advantage of distant reading.

In **multicycle indicators**, the indicator diagram is built up point-by-point from a large number of engine cycles. The Bureau of Standards Indicator (*N.B.S. Rept.* 107) operates on the balanced-pressure principle, with the cylinder pressure balanced against an external pressure source. The English Farnboro indicator, operating on this principle, has been refined and applied to airplane-engine research by the N.A.C.A. (N.A.C.A. *Tech. Note* 348). A balanced pressure indicator in which the balancing pressure is supplied by the engine itself and the cards are taken on an ordinary mechanical indicator has been developed by De Juhasz (*Instruments*, Mar., 1933).

Maximum pressure indicators are available for showing the maximum pressure in an internal-combustion engine cycle. A simple form uses a balancing spring to oppose the cylinder pressure. A contact and a neon-light flasher indicate the point of balance. The spring adjustment is a micrometer screw calibrated in pounds per square inch (Bacharach Industrial Instrument Co.).

Reducing Motions

To obtain the conventional indicator diagram, the drum of the indicator must be moved so as to give on a smaller scale an exact reproduction of the motion of the piston. A device accomplishing this is called a perfect reducing motion. Many devices used quite generally do not give a perfect motion.

The Pantograph (Fig. 34) is a theoretically perfect device and is actually accurate so long as there is no slackness at the numerous pinned joints. The point of attachment of the indicator cord B must be in the straight line joining the fixed point C with the connection on the cross head A. Figure 35 is a simple reduction motion that is nearly perfect when properly laid out. The pin D is attached to the cross head C, and the link BD connects the cross head to the oscillating arm AB. To convenient points, as 1, 2, or 3, the indicator cord is attached. If the arc XY in its extreme positions at the ends of the stroke reaches as much above the center line of motion of the pin D as it does below, the movement of the drum will be almost an exact duplicate of that of the piston. If the indicator motion is taken from the heavy dotted circular segment G instead of from a pin, the motion is more accurate. Figure 36 is also a simple device and is fairly accurate if AB is made equal to BC. The cord is attached to D.

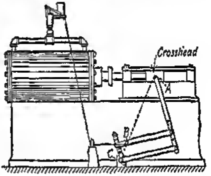

FIG. 34.—Pantograph Reducing Motion.

Figure 37 shows an accurate and simple reducing motion for attachment to the end of a crankshaft. The ratio of the lengths of the connecting rod and stroke of this device must be the same as the corresponding ratio in the engine. A similar device is shown in Fig. 38.

Reducing wheels may be attached either to the drum of the indicator or to some convenient part of the engine. Figure 39 shows a typical device. The large wheel receives the cord direct from the cross head,

of discharge C for a given orifice measurement depends on pipe size, diameter ratio, location of taps, and Reynolds number. Values are given in Fig. 19 for the product "$M \times C$" for "radius taps," applying to 2 and 16 in. pipe sizes, and interpolations may be readily made. (Fluid Meters, Part 1, gives extensive tables of coefficients to four places.) Diameter ratios greater than 70 percent (throat diameter to pipe diameter) are not recommended by the A.S.M.E. Code. Pressure loss due to the insertion of a thin-plate orifice is as follows:

Diameter ratio D_2/D_1	0.3	0.4	0.5	0.6	0.7
Pressure loss in percent of differential pressure	90	82	73	62	51

For metering viscous liquids (low Reynolds numbers), orifice coefficients change greatly, and available data are inadequate except for limited conditions (see Tuve and Sprenkle "Orifice Discharge Coefficients for Viscous Liquids," *Instruments*, Nov., 1933; Aug., Sept., 1935).

Intake and discharge orifices, located at the end of a pipe instead of in a continuous run, are very convenient, especially for air measurement.

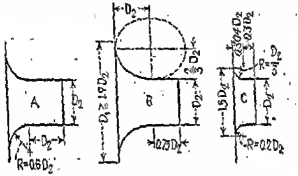

FIG. 20.—Types of Flow Nozzle.

A, A.S.M.E. Standard for displacement compressors.
B, A.S.M.E. long radius nozzle for low diameter ratios.
C, International Standards Association (I.S.A.) nozzle.

For a review of existing data, see Marks, "*Square-edged Inlet and Discharge* Orifices for Measuring Air Volumes in the Testing of Fans and Blowers," *Trans. A.S.M.E.*, Nov., 1936. In the absence of any generally accepted table of coefficients, it may be noted that a value of $C = 0.60$ is probably correct within 1.5 percent for either intake or discharge orifices, for Reynolds numbers above 100,000 for any diameter ratio up to $D_2/D_1 = 75$ percent, and for corner taps (at the orifice face), for flange taps (1 in. distant from face), or in the case of intake orifices for a tap 40 percent of the pipe diameter downstream. This tolerance is substantiated by Polson and Lowther (*Univ. Illinois, Eng. Expt. Stat. Bull.* No. 240) on orifices discharging from a plenum box.

The **flow nozzle** has the advantage over the thin-plate orifice of a more nearly constant coefficient of discharge, especially at high Reynolds numbers. But much less experimental work has been done on flow nozzles than on orifices, and moreover the form of the nozzle is not well standardized. Three proposed standards are shown in Fig. 20.

The A.S.M.E. Fluid Meters Report does not give any values of the coefficients for the short radius I.S.A. nozzle and gives only "tentative" coefficients for the long-radius nozzle. For high Reynolds numbers (above 400,000), a constant coefficient of discharge of 0.995 is given for both types A and B

and the cord on the small wheel is connected direct to the drum of the indicator. Ratio of diameters gives the reduction. Each reducing wheel is provided with a nest of rings to be put on the small wheel to change its diameter so that various reductions are possible to suit the stroke of the engine. The indicator drum is started and stopped by turning the knurled nut at the end of the shaft. The large wheel has a spring at its center to bring it back on the inward stroke. In engine testing for long periods, it is desirable to disconnect the cord connecting the large pulley with the cross head during the intervals between taking diagrams. Hooks like those shown in Figs. 40 and 41 are very convenient for this purpose, particularly if attachment of the cords can be made to a pin on the cross head. The Trill hook

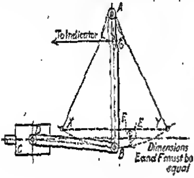

FIG. 35.

Simple Indicator Reducing Motions.

FIG. 37.

FIG. 38.

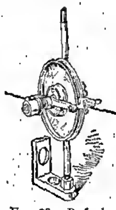

FIG. 39.—Reducing Wheel.

FIG. 40.

FIG. 41.

(Fig. 40) is intended to be held between the thumb and finger, about an inch from the end of the instroke, so that the pin or standard on the cross head strikes the straight part of the hook, and immediately the pin or standard will be caught. The hook shown in Fig. 41 is used in the same way. The hook is of spring brass and is held so that the pin or standard A on the cross head strikes the crotch when about 1 in. from the end of its stroke and opens the hook and assumes the dotted position when in operation. In disengagement, the hook is slipped off the end of the pin. Unless some special form of hook is used, as described, it is difficult to connect the cord when a diagram is to be taken, and the cord is likely to get tangled in moving parts of the engine or to be broken. Such difficulties can often be avoided, particularly in the case of such devices as Figs. 37 and 38, by continuing the cord from its

(Fig. 9). At lower values of the Reynolds number, the "tentative" coefficients of discharge C for type B are as follows:

Reynolds number ($DV\rho/\mu$) throat conditions	10,000	20,000	30,000	50,000	75,000	100,000	200,000	300,000
Nozzle coefficient, C	0.943	0.956	0.961	0.968	0.973	0.978	0.986	0.992

These coefficients are for pressure taps one diameter upstream and in the parallel throat portion downstream (not less than ¾ in. from the end). For nozzles with free open discharge, the tentative coefficients are about 0.5 percent lower. **Pressure loss** due to the insertion of a flow nozzle is about the same as that for an orifice, because there is no diverging tube to give an orderly transformation from velocity pressure to static pressure.

Venturi meters are usually made with diameter ratios of 25 to 50 percent, with an entrance cone of 21 deg, and a cylindrical throat section provided with piezometer openings (see p. 259). The standard Herschel design has an exit cone with a total included angle of 5 to 7 deg giving an over-all **pressure loss** of 10 to 20 percent of the differential pressure. This low

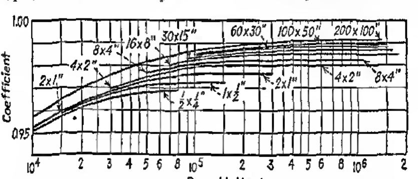

Fig. 21.—Discharge Coefficients for Venturi Tubes (as Manufactured by Builders Iron Foundry and Simplex Valve and Meter Co.).

pressure loss is the main reason for using a Venturi instead of a flow nozzle. Shorter diverging cones may be obtained; a short cone increases the over-all pressure loss but it does not affect the discharge coefficient. **Coefficients of discharge** for Venturi tubes depend on Reynolds number, but also vary *somewhat with diameter ratios and with pipe size.* With throat diameters of 1 in. or more, metering water, the coefficients are practically constant above 10 fps throat velocity, as follows:

Size of Venturi, in.	2 × 1	4 × 2	8 × 4	16 × 8	30 × 15	100 × 50
Discharge coefficient	0.976	0.980	0.983	0.986	0.988	0.990

Coefficients of discharge for general application in the range of Reynolds numbers from 10,000 to one million are given in Fig. 21. (For coefficients outside of this range see A.S.M.E. Fluid Meters Report, Part 1, p. 100.) The interior surfaces of Venturi tubes must be very carefully finished and must be kept clear of dirt or sediment. Very large Venturi tubes have been made with cones of smooth-surfaced concrete, and units as large as 42 × 24 ft are in service.

Pitot tubes are more often used for pipe traverses than for fixed-position meters (see pages 279 and 280). Many forms of Pitot tubes are used, and various standards in air and gases are somewhat different from those used in water. The standard Pitot tube for fan tests is shown in Fig. 22. Almost

point of attachment to the reducing motion closely past the indicator drum to a pipe or simple bracket that may serve as a stationary support. Between the indicator and this last support, a spiral or helical spring of rather light wire or a heavy rubber band is attached to the cord and will keep it taut and in motion. If now a ring is attached to the cord close to the indicator and between it and the reducing motion, this ring will be continually in motion but it will not be difficult to hitch into it the hook on the portion of cord connected to the indicator drum. This method is particularly recommended in every case where wire is used instead of cord.

Some indicators are provided with a detent or device for engaging a pawl in teeth on the circumference of the drum near the bottom and stopping the drum. Obviously, the pawl must engage when the cord is pulled out to the end of its stroke. On the return stroke, the cord will flap about and possibly catch on something and be broken on the next outward stroke. The best way to prevent this is to keep the string always taut by using a helical spring or rubber band attached to some fixed point, as explained above.

In all types of reducing motions except those in which the cord is taken off on a tangent to an arc of a circle, the direction of the cord as it moves back and forth at its point of attachment to the reducing motion must be parallel to the movement of the engine piston. Reducing motions are sometimes made inaccurate by not locating auxiliary pulleys properly to give the cord its proper direction.

DETERMINATION OF THE MOISTURE IN STEAM

Sampling steam is the most uncertain part of a determination of steam quality. The **standard sampling nozzle** should preferably be made of ½ in. pipe and should extend across the steam main, within ½ in. of the opposite wall. The end of the nozzle should be closed, the steam entering through a row of ⅛ in. holes, facing directly against the stream. For main steam pipes smaller than 5 in., the inlet holes are to be ½ in. apart; for larger sizes, six holes are to be used. The holes at each end should be about ½ in. from the pipe wall.

The most desirable **location for a sampling nozzle** is in a pipe in which the steam flows vertically downward, far removed from a valve, elbow, or other disturbing element. Second choice is in a pipe in which steam ascends vertically, far from a valve or fitting. A pipe bend or a horizontal pipe should be avoided, but if no other location is possible the sample should be taken at the entrance to a bend or immediately following a valve or other mixing device in a horizontal pipe. There can be no assurance that the sample will be representative in these latter cases.

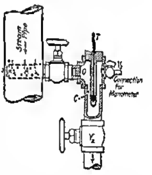

FIG. 42.—Throttling Calorimeter.

The **throttling calorimeter** is most commonly used for determining the moisture in steam. The calorimeter (Fig. 42) consists of a sampling nozzle A, a throttling orifice O, and a thermometer T located in a well which is entirely surrounded by the steam in the expansion chamber C. If the expansion chamber is not open to atmosphere, the pressure within the chamber is obtained from a manometer or gage connected at V_2. Two other essentials are the measurement of the pressure (or the temperature) in the saturated steam main and an ample insulation covering the calorimeter and connections.

INDETERMINATE FORMS

In the following paragraphs, $f(x)$, $g(x)$ denote functions which approach 0; $F(x)$, $G(x)$ functions which increase indefinitely; and $U(x)$ a function which approaches 1; when x approaches a definite quantity a. The problem in each case is to find the limit approached by certain combinations of these functions when x approaches a. The symbol $\doteq$ is to be read "approaches."

CASE 1. "$\frac{0}{0}$." To find the limit of $f(x)/g(x)$ when $f(x) \to 0$ and $g(x) \to 0$, use the theorem that $\lim \frac{f(x)}{g(x)} = \lim \frac{f'(x)}{g'(x)}$, where $f'(x)$ and $g'(x)$ are the derivatives of $f(x)$ and $g(x)$. This second limit may be easier to find than the first. If $f'(x) \doteq 0$ and $g'(x) \to 0$, apply the same theorem a second time: $\lim \frac{f'(x)}{g'(x)} = \lim \frac{f''(x)}{g''(x)}$; and so on.

CASE 2. "$\frac{\infty}{\infty}$." If $F(x) \to \infty$ and $G(x) \to \infty$, then $\lim \frac{F(x)}{G(x)} = \lim \frac{F'(x)}{G'(x)}$, precisely as in Case 1.

CASE 3. "$0 \cdot \infty$." To find the limit of $f(x) \cdot F(x)$ when $f(x) \to 0$ and $F(x) \to \infty$, write $\lim [f(x) \cdot F(x)] = \lim \frac{f(x)}{1/F(x)}$, or $= \lim \frac{F(x)}{1/f(x)}$; then proceed as in Case 1 or Case 2.

CASE 4. "0^0." If $f(x) \to 0$ and $g(x) \to 0$, find $\lim [f(x)]^{g(x)}$ as follows: let $y = [f(x)]^{g(x)}$, and take the logarithm of both sides thus:

$$\log_e y = g(x) \log_e f(x);$$

next, find $\lim [g(x) \log_e f(x)]$, $= m$, by Case 3; then $\lim y = e^m$.

CASE 5. "1^∞." If $U(x) \to 1$ and $F(x) \to \infty$, find $\lim [U(x)]^{F(x)}$ as follows: let $y = [U(x)]^{F(x)}$, and take the logarithm of both sides, as in Case 4.

CASE 6. "∞^0." If $F(x) \to \infty$ and $f(x) \to 0$, find $\lim [F(x)]^{f(x)}$ as follows: let $y = [F(x)]^{f(x)}$, and take the logarithm of both sides, as in Case 4.

CASE 7. "$\infty - \infty$." If $F(x) \to \infty$ and $G(x) \to \infty$, write $\lim [F(x) - G(x)]$ $= \lim \frac{\frac{1}{G(x)} - \frac{1}{F(x)}}{\frac{1}{F(x) \cdot G(x)}}$; then proceed as in Case 1. Sometimes it is shorter to expand the functions in series. It should be carefully noticed that expressions like $0/0$, ∞/∞, etc., do not represent mathematical quantities.

CURVATURE

The **radius of curvature** R of a plane curve at any point P (Fig. 7) is the distance, measured along the normal, on the concave side of the curve, to the **center of curvature**, C, this point being the limiting position of the point of intersection of the normals at P and a neighboring point Q, as Q is made to approach P along the curve. If the equation of the curve is $y = f(x)$,

$$R = \frac{ds}{du} = \frac{[1 + (y')^2]^{3/2}}{y''}$$

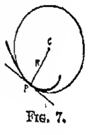

FIG. 7.

where $ds = \sqrt{dx^2 + dy^2}$ = the differential of arc, $u = \tan^{-1}[f'(x)]$ = the angle which the tangent at P makes with the x-axis, and $y' = f'(x)$ and $y'' = f''(x)$ are the first and second derivatives of $f(x)$ at the point P. Note that $dx = ds \cos u$ and $dy = ds \sin u$. The curvature, K, at the point P, is $K = 1/R = du/ds$; that is, the curvature is the rate at which the angle u is changing with respect to the length of arc s. If the slope of the curve is small, $K \approx f''(x)$.

If the equation of the curve in polar co-ordinates is $r = f(\theta)$, where r = radius vector and θ = polar angle, then

$$R = \frac{[r^2 + (r')^2]^{3/2}}{r^2 - rr'' + 2(r')^2},$$

where $r' = f'(\theta)$ and $r'' = f''(\theta)$.

The **evolute** of a curve is the locus of its centers of curvature. If one curve is the evolute of another, the second is called the **involute** of the first.

INDEFINITE INTEGRALS

An integral of $f(x)dx$ is any function whose differential is $f(x)dx$, and is denoted by $\int f(x)dx$. All the integrals of $f(x)dx$ are included in the expression $\int f(x)dx + C$, where $\int f(x)dx$ is any particular integral, and C is an arbitrary constant. The process of finding (when possible) an integral of a given function consists in recognizing by inspection a function which, when differentiated, will produce the given function; or in transforming the given function into a form in which such recognition is easy. The most common integrable forms are collected in the following brief table; for a more extended list, see B. O. Peirce's "Table of Integrals" (Ginn & Co.).

General Formulæ

1. $\int a\,du = a\int du = au + C$ 2. $\int (u + v)dx = \int u\,dx + \int v\,dx$

3. $\int u\,dv = uv - \int v\,du$ 4. $\int f(x)dx = \int f[F(y)]F'(y)dy,\ x = F(y)$

5. $\int dy \int f(x,y)dx = \int dx \int f(x,y)dy.$

Fundamental Integrals

6. $\int x^n dx = \dfrac{x^{n+1}}{n+1} + C$; when $n \neq -1$

7. $\int \dfrac{dx}{x} = \log_e x + C = \log_e cx$ 8. $\int e^x dx = e^x + C$

9. $\int \sin x\,dx = -\cos x + C$ 10. $\int \cos x\,dx = \sin x + C$

11. $\int \dfrac{dx}{\sin^2 x} = -\cot x + C$ 12. $\int \dfrac{dx}{\cos^2 x} = \tan x + C$

13. $\int \dfrac{dx}{\sqrt{1 - x^2}} = \sin^{-1} x + C = -\cos^{-1} x + c$

14. $\int \dfrac{dx}{1 + x^2} = \tan^{-1} x + C = -\cot^{-1} x + c$

Rational Functions

15. $\int (a + bx)^n dx = \dfrac{(a + bx)^{n+1}}{(n + 1)b} + C$

The connection between sampling nozzle and orifice should be as short as possible.

The **steam quality** or relative dryness may be obtained from an enthalpy-entropy chart (see p. 326). Throttling is represented by a vertical line on the chart. The quality (or superheat) of the original steam sample is obtained by locating on the chart the downstream calorimeter temperature and absolute pressure, then tracing vertically to the line representing the upstream pressure. The temperature or moisture content at the latter intersection represents the condition of the original sample. For greater accuracy, a larger chart may be used, or the quality x may be calculated from the equation

$$x = (h_2 - h_f)/h_{fg}$$

where h_2 is the enthalpy of superheated steam at calorimeter pressure and temperature; h_f the enthalpy of the liquid of the high-pressure steam entering calorimeter; and h_{fg} the latent heat of vaporization of the high-pressure steam. The range of the throttling calorimeter is limited, but it increases with higher pressures. At 125 lb per sq in. abs, the range is 0 to 4.6 percent moisture, and at 400 lb its range is 0 to 7.3 percent. The accuracy of the throttling calorimeter itself is high. The A.S.M.E. Code states that its accuracy can be within 0.2 percent.

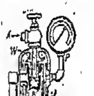

Fig. 43.—Separating Calorimeter.

Separating calorimeters may be used for determining the quality of steam which contains more moisture than can be determined by a throttling calorimeter. A simple form is shown in Fig. 43. The moisture is removed from the sample of steam by mechanical separation just as in the ordinary steam separator installed in the steam mains of a power plant. Steam enters at A, passes down through the vertical pipe into the perforated basin B, from which the dry steam escapes through a narrow slot near the top into the jacket J, while the moisture is deposited at the bottom of the vessel V. The volume or weight of the moisture can be determined from the height of the water in the gage glass G. Dry steam from the jacket J is discharged from the orifice O and must be condensed and weighed in a vessel containing cold water. The percentage of moisture is found by dividing the weight of water collected in the vessel V by the sum of the weight of steam condensed and the weight of water collected in V.

The separating calorimeter described above is effective in removing practically all the moisture in steam when the pressure is not lower than 25 lb per sq in. gage pressure. For lower pressures, such calorimeters may not take out more than 80 percent of the moisture. Consequently, for determinations of moisture in low-pressure steam, a throttling calorimeter should be attached to the discharge of the separating calorimeter. A throttling calorimeter discharging into the atmosphere has very little capacity when used with low steam pressures. By making it discharge into a receiver in which a high vacuum is maintained, the throttling portion of the calorimeter will evaporate 2 to 3 percent of moisture. A combination separating and throttling calorimeter for low-pressure steam is described in *Trans. A.S.M.E.*, 1910, p. 76.

The A.S.M.E. Power Test Codes, Instruments and Apparatus, Part 11, "Determination of Quality of Steam," describes various types of calorimeters including several forms of the throttling and separating types. Combina-

from these may, in some cases, not be disadvantageous, and where velocity-distance lag alone is present may even be helpful. In open-and-shut or proportional-with-reset controllers, good results can be obtained consistently only if the controllers are able to recognize minute changes in measured variable and institute effective corrective action on them. A correctly designed and built controller of simple construction will successfully handle applications that require a much more complicated mechanism, if the latter has been designed and built without sufficient attention having been paid to keeping the force-friction ratio amply large.

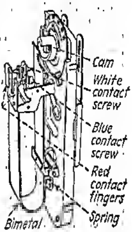

Fig. 1.—Thermostat.

Moving parts should be light, and mounting brackets should be rigid. Unbalanced forces, sometimes unavoidably present, should be prevented from shifting in direction. Mechanism should be arranged so that it takes up lost motion always in the same direction. Power must be provided to overcome friction or to reduce it to a negligible minimum. When mechanical force is necessary, relays should be used.

Force is necessary to produce motion of a final-control element or of a relay. The force developed by the permissible small amount of deviation of the measured variable in the ordinary industrial controller is almost negligible. In some types, such as pyrometer controllers, this force is actually so small as to be incapable of actuating even the most sensitive relay directly. In such cases, resort must be had to detecting the position of a pointer intermittently, which complicates the mechanism and may prevent successful results on processes that can change rapidly.

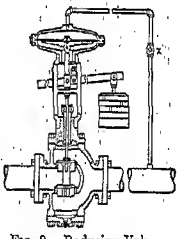

Fig. 2.—Reducing Valve.

Where the force developed by permissible small deviations of a controller element is large enough to be used directly, it is absolutely necessary that its full amount be used to move either the final control element directly, in the case of a self-actuated controller, or the first relay, in servo-actuated types, if the controller is to fulfill its function to its maximum possible extent.

Types of control mechanisms are illustrated in Figs. 1–4, showing different modes of control action and types of actuating mediums.

The common domestic **thermostat** shown in Fig. 1 is an example of an "on-and-off" controller of the "differential-gap" type. When temperature decreases, the bimetallic strip (red) moves toward the two contacts (blue and white). A relay in a standard electrical lockup circuit closes when both contacts are made and opens when both are broken. The red-to-white contact finger is flexible and after closing its contact permits further travel of the bimetallic strip until the red-to-blue contact closes. The difference in travel is ordinarily equivalent to approximately 1½ deg F, which is the "differential gap" and represents the temperature change necessary to start and stop the burner of the house heating system.

The weight-loaded reducing valve in Fig. 2 acts as a proportional regulator, as the change in effective area of the diaphragm through its stroke produces the proportional effect. By pinching off the valve x in the connecting line between the diaphragm and the pressure line, this type is made to act as a variable-rate controller, as described under B(3).

tions of the throttling and separating calorimeters are also covered in the Code. Specific instructions for steam sampling, for calibration of calorimeters, and for calculation of results are given.

ANALYSIS OF FLUE GASES AND EXHAUST GASES

For the analysis of flue gases in a power plant by chemical means, an **Orsat apparatus** is generally used. It consists of a graduated tube or burette (surrounded by a water jacket) to receive and measure the volume of the gas. This burette is connected by a manifold of glass or hard rubber to "pipettes" containing the liquids for absorbing CO_2, O_2, and CO. The pipettes are each a little more than half-filled with the absorbing liquid. Water well saturated with CO_2 is ordinarily used for displacement of gases. For accurate work, brine or mercury should be used. To absorb CO_2, the gases are first passed into a pipette containing a solution of one part by weight of KOH (caustic potash) in two parts by weight of water. Some form of surface-contact pipette or bubbling pipette should be used. Free oxygen is similarly absorbed by a mixture of pyrogallic acid and KOH, prepared by pouring 5 g of powdered pyrogallic acid into the pipette and then adding 100 cc of the KOH solution as prepared for the first pipette. Some engineers use solutions containing a much larger proportion of pyrogallic acid to make the absorption more rapid, but this is not recommended, as stronger solutions are likely to evolve CO in the presence of free oxygen. A more rapid oxygen reagent is chromous chloride. This absorbent may be purchased, all prepared, under various trade names.

The solution for absorbing CO is cuprous chloride (Cu_2Cl_2), which should be made in a glass bottle having a well-fitting glass stopper, greased to make it airtight. It can be made by pouring 25 g of copper oxide into the bottle and adding about 500 cc of commercial hydrochloric acid (sp. gr. about 1.1 being obtained by adding *to water* an equal volume of chemically pure acid). To this solution is added 150 to 200 g of copper wire cut in lengths to extend from the bottom to the top of the bottle. The solution is then allowed to stand in the bottle till clear, when it is ready for use in gas analysis. By filling the bottle from time to time with acid and adding copper wire as needed to replace that dissolved, a supply of the solution will always be on hand. The KOH solution will absorb 20 times its volume of CO_2 before requiring renewal, the pyrogallic solution will absorb efficiently only twice its volume of oxygen, and cuprous chloride only an equal volume of CO. The solution for absorbing oxygen, therefore, requires very frequent renewal.

The A.S.M.E. Power Test Codes, Instruments and Apparatus, Part 10, "Flue and Exhaust Gas Analyses," gives detailed information both on equipment and procedure.

The most common errors in the use of gas apparatus are due to leakage. The apparatus should be carefully tested before starting an analysis by filling each pipette with the solution up to a mark on its capillary tube, and then, after closing all stoppers and pinch cocks, carefully observing the volume of gas at atmospheric pressure on the scale of the burette. The water bottle is then placed on top of the case so that the gas in the burette and in the yoke will be under pressure for about 5 min, after which the volume of gas is again measured. If there is no leakage the volume will remain constant. If there is leakage a drop of water should be put at each place where there might be leakage. Bubbles of gas will indicate where the apparatus is not air-tight. Extreme care should be taken in arranging for and in collecting the samples of flue gas for analysis. A continuous sample should be collected at a uniform rate during the whole period of the test. Many engineers use for a collecting tube a ½ in. pipe open at the end,

The operation of Type B(6)—proportional control with automatic reset—may be followed from Fig. 3, which shows a pneumatically operated instrument.

Assume that the instrument has been in successful control and conditions are balanced so that 8 lb pressure exists in the controlled valve diaphragm motor line (15). The same pressure will exist in bellows (7) and (13).

If an upset occurs, making the element read lower, flapper (4) will uncover nozzle (6), reducing the pressure on diaphragm (11), since air can now flow out of nozzle (6) faster than it can flow in through restriction (12). This will cause bellows (11) to collapse and admit pressure through valve (17), until the increased pressure in bellows (7) causes it to pull the nozzle (6) against the flapper once more.

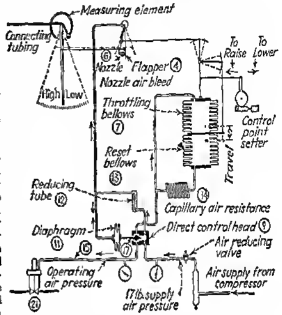

FIG. 3.—Proportional Control with Automatic Reset.

Bellows (7) is spring loaded so that the air pressure change is strictly proportional to the nozzle deflection, producing a uniform throttling range.

This increased pressure immediately starts to bleed through restriction (14) to bellows (13), which is equal in area to, and opposes the motion of, bellows (7). As the pressure in bellows (13) increases, nozzle (6) will be forced away from the flapper (4). However, when this happens, valve (17) in control head (9) will be opened further, raising the pressure in bellows (7) as much as is necessary to keep the nozzle just tangent to the flapper. This resetting effect will continue until the pressure on the diaphragm of the controlled valve (21) has increased (or decreased) enough to produce the new valve opening which will return the temperature (pressure, flow, liquid level) to the set point. When, and only when, this occurs, pressures in bellows (7) and (13) become equal, and equilibrium is again restored.

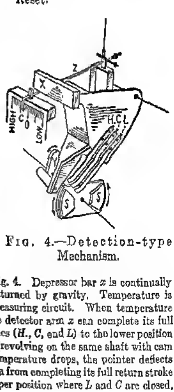

FIG. 4.—Detection-type Mechanism.

A detection-type mechanism is illustrated in Fig. 4. Depressor bar x is continually being raised by the motor-driven cam y and returned by gravity. Temperature is measured by the pointer c, of a potentiometer measuring circuit. When temperature rises, the pointer deflects toward "high," and the detector arm z can complete its full downward stroke. This throws the contact brushes (H., C, and L) to the lower position where H and C are closed by the contact disks S (revolving on the same shaft with cam y), thus reducing the heat supply. When the temperature drops, the pointer deflects toward "low," thereby preventing the detector arm from completing its full return stroke by gravity, holding the contact brushes in the upper position where L and C are closed, and thus increasing the heat supply. This produces off-and-on or two-position control action. Similar mechanisms are used to produce practically any of the modes of control discussed.

which is carefully located so that the open end will be in the unobstructed flow of the gases.

The A.S.M.E. Code states that probing the gas passage with a single tube gives questionable results and that a perforated pipe is worthless. The Code recommends taking individual simultaneous samples from different points in the cross-sectional area, analyzing these separately, and averaging the results. Other approved methods are: (1) composite sampling with equivalent flow from each individual tube; (2) a branched averaging sampler (or a spider) so constructed that each portion of the sample travels through the same length of pipe; (3) an open-end portable tube of ½ in. pipe, which is slowly and steadily moved across the area during sampling. With stationary sampling tubes, not less than one open-end tube is required for each 18 sq ft of gas passage, with *not less than 3 sampling points*. In large ducts, the sampling locations should be at least 3 ft from the walls.

For sampling from exhaust pipes of internal-combustion engines, a sampling tube of ⅜ in. pipe is to be extended to the middle of the exhaust pipe, with the end of the tube cut at an angle to its length and the opening turned against the gas flow. A small steam or water jet "ejector" or aspirator should be used for securing a continuous flow of gas into the collecting vessel. Usually it is most convenient to collect the gas over water, which must be saturated with the gas in order to avoid differential absorption of the constituents of the gas. Fresh samples should be taken directly from the collecting vessel into the analyzer if possible, without intervening storage time. To make sure that all the gas has been absorbed by each reagent, the process should be repeated until readings agree within $\frac{1}{10}$ percent. With fairly fresh solutions, 2 to 3 min are required to absorb all the CO_2 or CO, although 5 to 7 min may be required to determine the oxygen. It is desirable to replace the pyrogallic solution frequently.

Several semiautomatic **portable analyzers** are available, by which rapid determinations of CO_2 only may be made. These indicators actually measure the vacuum formed in a closed absorption chamber, and the vacuum gage is calibrated in percentage of CO_2.

One type of **automatic apparatus** in common use absorbs CO_2 continuously and registers the percentage content. In practically all such apparatus, KOH is the absorbent. Another type depends for its action on the difference between the specific weight of air and of flue gas, which is approximately proportional to the percentage by volume of CO_2 in the gas ("econometer" method). Of the two methods, that of absorption is the better. One automatic device depends upon the change of pressure in a stream of flue gas flowing through two apertures, when the CO_2 is absorbed.

Electric CO_2 Meter. **Thermal-conductivity methods** have come into use for measuring the amount of CO_2 in flue gases and also for evaluating the combustion conditions in internal-combustion engines.

The advantage of the method is that no materials are used which require replacement at frequent intervals. A suitable apparatus consists, in essential parts, of two gas cells marked *A* and *B* in Fig. 44, each of which contains a spiral of platinum wire, with provision for supplying electric current to each of the platinum spirals from a storage battery. The cell *A* is filled with air and sealed for a comparison standard. The other cell *B* is arranged so that the sample of flue gas to be tested passes through it. The current from the storage battery *S* is controlled to a constant value by means of the rheostat *R* and the ammeter *A*. The current from the battery *S* as shown in Fig. 44 passes through the platinum spirals *A* and *B* on one side and the "ratio coils" *C* and *D* on the other. If the gases surrounding the wires are alike in thermal conductivity, heat transmission to the metal walls of the two cells will be equal, and the platinum spirals will be heated to the same temperature.

The thermal conductivity of CO_2 differs from that of air by approximately 40 percent, and since the other constituents of flue gas, such as carbon monoxide, methane, nitrogen, and oxygen, have substantially the same conductivity as air, the difference in temperature under these conditions between the platinum spirals *A* and *B* will vary with the amount of CO_2 in the sample of flue gas being tested.

WELDING

Welding may be divided into forge welding, arc welding, gas welding, resistance welding, and thermit welding.

Arc Welding

Arc welding may be subdivided into metal-arc welding with bare electrodes or with coated (shielded-arc) electrodes, or in a reducing gas flame; atomic-hydrogen arc welding; carbon-arc welding, shielded or unshielded; and sub-

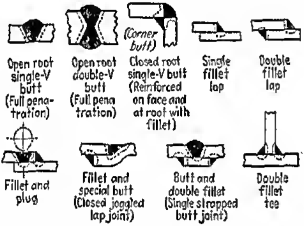

FIG. 1.—Forms of Welds and Joints.

merged arc. Further differentiation is based on whether the current is direct or alternating and whether the operation is manual, semiautomatic, or automatic.

In **metal-arc welding** an arc passes between a wire or rod of suitable composition, called the electrode, and the parts to be welded. The parts to be joined are made one side of an electric circuit, the other being the electrode. The metal is fused at both ends of the arc and the fused electrode deposited in the joint until the latter is properly filled. Various joints are illustrated in Fig. 1. Power is usually supplied by a transformer or by a generator delivering an open-circuit voltage ranging from 35 to 95 volts.

The arc should be short in order to avoid oxidation and the inclusion of harmful gases and to secure proper penetration. Some arc-welding generators are so designed that the arc will be extinguished after its length exceeds a safe limit. The normal arc voltage is so low (15 to 20 volts for bare wire and 22 to 40 volts for heavily coated wires) as compared with the striking or open voltage (35 to 95 volts) that machines of special design must be employed. A skillful operator can do good welding on a constant potential, 110 to 550 volt circuit, with a suitable resistance in series, but this process

The arrangement of battery, rheostat, and the four resistances, with the addition of the galvanometer G and the resistance F and H, as shown in Fig. 44, make up a circuit that is suitable for resistance measurements by the Wheatstone-bridge method. In the operation of this device, if the resistances are "balanced" when air is passed through the platinum spiral B, the bridge will be thrown out of balance when flue gas containing any appreciable amount of CO_2 passes through the platinum spiral B, and there results a deflection of the galvanometer G nearly proportional to the amount of CO_2 in the sample.

Heat is conducted away from the platinum spiral in the cell B by the flue gas less rapidly than from the filament in the air cell A. With the same flow of electric current in the two platinum spirals, the spiral exposed to the flue

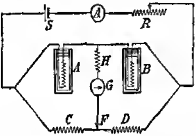

FIG. 44.—Diagram of Wheatstone Bridge Circuit.

gas will be hotter than the one in the air cell. Since the resistance of platinum changes with the temperature, the Wheatstone bridge will be unbalanced as soon as any CO_2 is present in the gas cell B. The scale on the galvanometer may be marked so that the pointer of the galvanometer will indicate on it directly the percentage of CO_2 in the flue gas. This type of apparatus may be made either as an indicating or a recording instrument. Convenient portable units of the thermal conductivity type are available, both for furnace gases and for engine-exhaust gases. The indicator scales on the latter may be calibrated in terms of air-fuel ratio instead of CO_2.

An electric **CO indicator** has been designed on the same general principles as the electric CO_2 meter. The operation of the CO meter is based on the catalytic action of a heated platinum wire in producing combustion of CO with oxygen. The essential parts of the instrument are two platinum wires which are heated by an electric current. These wires pass through the center of cylindrical chambers, each being in a separate metal block. One of the wires is the "measuring wire," which is in the chamber through which the sample of gas passes, and the other is the "comparison wire," which is maintained at a constant temperature by the electric current. A small amount of air is admitted to the cylindrical chamber surrounding the "measuring wire" to provide oxygen for combustion. The catalytic action causes the CO and the hydrogen in the flue gas to burn along the surface of the "measuring wire," thereby raising its temperature above that of the "comparison wire" and increasing the resistance of the "measuring wire" in almost exact proportion to the amount of CO and hydrogen gases in the sample of flue gas. The difference in resistance between the "measuring wire" and the "comparison wire" is measured by the Wheatstone-bridge method with a suitable galvanometer. The dial of the galvanometer is calibrated in percentage of CO.

is inefficient, as most of the power consumed is lost in the resistance. D-c generators may be constant-potential, constant-energy, or constant-current types.

The Welding Arc. The arc passes through incandescent vapor of the material forming the terminals of the arc gap. When direct current is used, one terminal (the anode) remains positive and the greater portion of the total heat is liberated at this terminal. When alternating current is used, approximately the same amount of heat is liberated at each terminal. *In the welding* of iron or steel the piece to be welded is usually made the positive terminal of the arc, but if very thin metal is being welded, it is advisable to reverse the polarity to prevent the arc burning through the metal. In welding with some coated electrodes and in the welding of manganese steel and bronze, it is often necessary to reverse the polarity and make the electrode positive. Excellent **arc welding** can be done **overhead** by a skilled operator.

The arc voltage determines the length of the arc with a given current. In manual welding with bare electrodes up to $\frac{3}{16}$ in. diam, it should seldom exceed 20 volts and with heavily coated wires it should not exceed 40 volts.

Shielded arc welding comprises those processes utilizing the electric arc for the fusion or deposition of metal in which the arc and metal are protected from the air. Shielding may be adapted to carbon-arc, metallic-arc, or hydrogen-arc processes in either the manual or automatic forms. Shielded-arc electrodes produce weld metal of high quality as a consequence of protection of the molten metal from the air. The effect of both oxides and nitrides in the weld metal is to cause brittleness or low ductility and, in some cases, low strength and poor corrosion resistance.

Shielding is accomplished by combinations of (1) the formation of a protruding flux sheath at the electrode tip; (2) the production of an inert or reducing atmosphere enveloping the arc and metal and (3) by providing a protective slag covering over the deposited weld metal. The molten slag in contact with the molten weld metal acts as a scavenger in removing oxides and other impurities from the weld. The fluidity of the metal is increased permitting higher rates of deposition.

Metallic deoxidizers are usually added to the coating to eliminate small amounts of oxygen and introduce into the weld metal various alloying elements for the production of high tensile strength, hardness, corrosion resistance, or other physical properties. The coatings cause the transfer of metal to take place as a stream of small globules rather than of large globules characteristic of bare metallic electrodes. **In automatic welding** it is necessary to effect some means of contact to the core metal for the introduction of *the welding current. Coatings are sometimes slit or pierced during the welding operation to provide for the contact.*

Carbohydrates are extensively used in coatings for steel electrodes for producing the **gaseous atmosphere.** Wood flour, pulp, paper, and cotton are commonly used and produce carbon monoxide and hydrogen in the arc.

Slag-forming materials for steel electrode coatings are mainly metallic oxides. Elements commonly employed are oxides or compounds of titanium, zirconium, silicon, magnesium, calcium, aluminum, iron, manganese, sodium, and potassium. Deoxidizers in common use are the ferroalloys of manganese, silicon, and titanium. These are largely oxidized during the welding process and form the corresponding oxides as constituents of the slag.

Stainless steel electrodes often contain small amounts of such materials as fluorides to aid in dissolving any chromium oxide which may be formed. Carbonaceous materials are kept at a minimum in these coatings to prevent an increase in the carbon content of the weld. Special elements for the stabilization of the stainless steel are sometimes included in the coating.

The most suitable mild steel **core wire** for shielded-arc electrodes is from high-grade rimmed steel. Specifications usually call for C, 0.13 to 0.18 percent; Mn, 0.40 to 0.60; Si, 0.06 max; S, 0.04 max; P, 0.04 max.

AUTOMATIC CONTROL

BY

J. B. McMAHON

(London)*, July, 1936.

Definitions. The A.S.M.E. Committee on Industrial Instruments and Regulators has tentatively defined an **automatic controller** (or regulator) as "an apparatus which measures the value of a quantity or condition which is subject to change with time and operates to maintain within limits this measured value." It consists essentially of two parts: (1) a **measuring device** comprising those elements which are involved in ascertaining and communicating to the controlling device an indication of the magnitude of the controlled variable, and (2) a **controlling device** comprising those elements which produce corrective action based upon indications supplied by the measuring means. A **variable** is a physical quantity subject to change with time.

The **set point** is that value of the variable which it is desired to maintain. A **final control element** is that portion of the controlling means which directly varies a control agent. A **control agent** is a medium in the process which is varied by the automatic controller and which affects the value of the controlled variable. The **adjusted flow** is the quantity rate of flow of the control agent.

Automatic Control and Automatic Operation. Confusion may arise from failure to distinguish between automatic operation and automatic control, particularly since the same equipment may be used in either service. A controller must (1) measure the variable (not necessarily producing a visual indication of it) and (2) produce corrective action when the variable departs from desirable limits, to bring it back within the desired limits.

Examples. A "safety controller" which shuts a process down when desirable limits are exceeded does not fulfill requirement 2. The common safety valve is a true automatic controller, as it fulfills both requirements. *Time-cycle controllers* which merely operate valves or other mechanisms in a certain fixed sequence are not true automatic controllers, since they do not measure a variable. A better name would be *time-sequence operator*. The simultaneous operation of two valves—as on fuel and combustion air—does not produce automatic ratio flow control of two fluids, unless each is operated by an independent flow controller which measures the effect of, and adjusts, its own valve independently of the other.

When a process or apparatus is such that constant attention is required, automatic control will produce results highly superior to hand control. Where occasional adjustments according to judgment, based on experience, will maintain the process or apparatus within the desired limits, manual

In arc welding in a reducing flame a cylindrical jet of gas surrounds the electrode and burns around the arc. Hydrogen, water gas, alcohol vapor, and a number of other gases have been tried with success. The welds are, in general, superior to the bare electrode welds, particularly as regards ductility. The operating voltage is higher than for simple metallic-arc welding so that the ordinary arc-welding generators will not serve.

In atomic-hydrogen arc welding a fine jet of hydrogen is forced through an arc formed between two tungsten electrodes. The arc breaks up the hydrogen molecules into hydrogen atoms, which recombine into molecules after passing through the arc, giving up the heat absorbed during dissociation in the arc. The result is a jet flame of hydrogen burning in a hydrogen atmosphere at a temperature higher than that of any other known flame but lower than that of the arc itself. The welding wire is fused in this flame and deposited in the joint exactly as in the case of gas welding. In cases where the plates to be welded are relatively thin, the edges are left square, butted together over a suitable backing, and fused together with the hydrogen jet without the use of any welding wire. The intensely reducing character of this hydrogen flame results in a nearly perfect weld, which, with suitable welding wire, is practically as good as the parent metal.

The magnitude of the arc current, and hence that of the hydrogen jet, is limited, because with heavy currents the tungsten electrodes burn away too rapidly. Thus the rate of welding-wire deposition is limited. Alloy steels, such as high-chromium and high-nickel steels, are readily welded by this process. As the heat applied to the joint is that of the atomic hydrogen jet flame and as this heat is controllable by varying the distance, much more delicate welding of thin parts can be done by this method than by direct arc welding with its higher temperature. In the latter case it is very difficult to avoid burning holes through thin stock.

The atomic-hydrogen arc process may be looked upon as the halfway point between arc and gas welding with some advantages over both, but as yet limited as to the rate of metal deposition. The arc voltage, both for striking and operating, is considerably higher than for either simple metal arc welding or for arc welding in a reducing flame, and alternating current is usually employed.

In carbon-arc welding, an arc is struck between a carbon (or graphite) electrode and the parts to be welded. The welding wire is fed into the arc and fused into the joint. For hand operation this requires two hands as in the case of gas welding or atomic-hydrogen arc welding. A fairly high rate of metal deposition is possible. In some cases the welding rod is laid in the joint groove and the carbon arc passed slowly along the joint until the fusion is complete. An automatic carbon-arc method, with a magnetically controlled arc, known as electronic-tornado welding, gives excellent results for thin plates in a flat position.

Automatic machines are available for nearly all the above described methods, although it is not easy to apply a welding-wire feeding mechanism to some of the coated electrodes, owing to the difficulty of getting electrical contact between the wire and the feeding rolls. Several methods have been devised for overcoming this difficulty. Oscillators are also available for varying the width of the weld.

Another method (Unionmelt) of producing shielded-arc welds automatically consists of applying powdered flux to the weld. This process employs welding currents of the order of 1,000 to 2,000 amp and makes possible the welding of plates 1½ in. thick and over in a single pass. A bare electrode

operation may be entirely adequate. In the latter case, satisfactory manual control of the end result may be secured much more readily by providing automatic controllers for all the individual variables affecting the end result, without direct application of automatic control to the end result itself.

The variables to be controlled should be selected with regard to (A) susceptibility to measurement; (B) significance of measurement; (C) susceptibility to automatic control, from the point of view of (1) economy, (2) consistent response to control action, and (3) consistent response to process; and (D) magnitude of process lags.

(A) Susceptibility to Measurement. Factors that can be measured in a laboratory may not be susceptible to continuous measurement by an industrial instrument; for example, definite chemical analysis may be the desired end result of a process, but, industrially, some physical effect of chemical variation, such as temperature, pressure, conductivity, or pH, may have to be used.

(B) Significance of Measurement. The variable, or variables, selected must be truly representative of changes in process conditions. Under constant operating conditions, some variables may become constant which do not vary quantitatively with changes in operating conditions. In the example under (A), all other variables affecting the end result must be held constant, so that the one selected may be truly significant. It might be said that the significant variable is the combined result of all the variables. As a further example, the temperature of vapors leaving the top, or of liquid leaving the bottom, of a fractionating column, which is separating a binary mixture into practically pure components, is not a satisfactory criterion for automatic adjustment of heat extracted from, or supplied to, the column; although it may be a satisfactory criterion of column operation.

(C) Susceptibility to Automatic Control. (1) Economy. In all cases, factors A and B must be satisfied for the successful application of automatic control. In many cases, however, A may be readily satisfied, but the obvious way of satisfying B may be very uneconomic. For example, the *characteristic curve* of a centrifugal pump and the kind of head against which the pump discharges (whether mostly static or mostly friction head) determine whether it is more economic to locate the controlled valve in the discharge of, or in a by-pass around, the pump.

(2) Consistent Response to Control Action. In complicated processes, response of adjusted flow rate to the corrective action of the controlling means must be reasonably consistent. For example, flow-line pressure drop and outside influences (such as the dumping action of steam traps and variations in pump speeds due to variable frictions) must not be excessive in their effects.

(3) Consistent Response of Process. Under some operating conditions, the measurement of the controlled variable may be significant but become insignificant under very slight changes in operating conditions. For example, both above and below ebullition, temperature is a significant measure of the quantity of heat in water or steam, but not at the point of change of state. Nor is temperature significant for the heat content of steel at the decalescence point.

(D) Process Lags. All automatic control is directed toward satisfying some demand by a corresponding supply. Process lag frequently prevents this from being done directly. As an example, the true measure of the load

is used, and the powdered flux is applied either between dams erected along the joint or from a hopper around the arc as the weld progresses. This process of welding produces extremely high welding speeds and welds with physical properties comparable to those made with the highest quality manual shielded-arc electrodes.

With automatic welding the arc length and other variables are accurately controllable, labor is saved, and the speed of welding can be greatly increased. It is readily applicable only to fairly simple shapes but has already found a large field of usefulness in production work.

In **semiautomatic arc-welding machines** the feed of the electrode and the arc length are under automatic control, but the "travel" or movement of the arc along the seam is under hand control. This largely eliminates the demand for skill on the part of the operator and is applicable to many situations where the full automatic machine could not be used.

Where **heavy sections** are to be **welded**, it is desirable to deposit the weld metal in a series of layers. When the first layer is deposited, all scale and slag should be removed before depositing the second layer. Peening of each layer with an air tool before depositing a new one not only removes the surface scale but stretches the deposited metal, removing any cooling shrinkage. Welds deposited in two or more layers are generally better than those deposited with a single layer, because the second and subsequent layers have a tendency to partly anneal the preceding layers, and a joint of improved structure will result.

Welding Technique and Procedures

A table of the average recommended welding currents for the gas-producing electrode is as follows:

		3/32	1/8	5/32	3/16	1/4	5/16	3/8
Electrode diam, in.		3/32	1/8	5/32	3/16	1/4	5/16	3/8
Amperes	Flat	60	120	150	175	250	325	425
	Vertical and overhead	60	110	140	160			

A table of the average recommended welding currents for the flat position, with heavy slag-producing electrodes is as follows:

Electrode diam, in.	1/8	5/32	3/16	1/4	5/16	3/8
Amperes	130–150	160–180	200–260	300–400	400–600	500–900

Typical automatic welding speeds obtained on butt- and fillet-welded joints with bare, wash-coated or dust-coated types of electrodes are given in Table 1.

Table 1. Automatic Welding Currents and Speeds

Plate thickness	Joint design	Electrode diam., in.	Current, amp	Passes	Speed, in. per min
18 gage	Square butt	1/8	110–180	1	25–33
14 gage	Square butt	1/8–5/32	150–210	1	18–26
10 gage	Square butt	5/32	180–230	1	12–20
3/16 in.	Square butt	3/16	225–300	1	8–13
1/4 in.	60° single V	3/16	225–300	2	5–8
1/2 in.	60° single V	3/16 & 1/4	240–350	3	2–3
3/4 in.	60° single V	3/16 & 1/4	240–350	5	1.5–2.0
1/4 in.	Fillet weld	3/16	200–280	1	16–19
3/8 in.	Fillet weld	1/4	250–300	1	8–10
1/2 in.	Fillet weld	1/4	250–300	2	5.8–6.5
3/4 in.	Fillet weld	1/4	260–325	3	2.5–3.0

(demand) on a turbogenerator may be the displacement of the governor measuring element, but it is usually impractical to attempt to control the fuel to the boiler directly from this effect, because of the intervening energy storage capacities and resistances to energy flow.

Self-regulation

Self-regulation may be positive, neutral, negative, or critical.

(*a*) **Positive processes** possess the property of being inherently self-balancing. Examples are (1) the temperature of water leaving a continuous hot-water heater varies with the demand, and (2) in an open tank through which water is flowing, every rate of inflow will produce the water height necessary to produce an outflow equal to the inflow.

(*b*) **Neutral processes** do not tend to balance themselves or to become progressively unbalanced. As an example, if a vessel, such as that in the last example, has superimposed on the water a high extraneous gas or vapor pressure, as in a high-pressure boiler drum, there will be very little relation between water height and rate of outflow. Any discrepancy between inflow and outflow will result in the vessel flooding or going dry. There will be little effective self-correction.

(*c*) In **negative processes**, any tendency to become unbalanced is progressive. For example, a liquid charged to a chiller by a centrifugal pump will tend to become more viscous if the rate of flow drops for any reason; this will tend to slow down the rate of flow, chilling it still more, etc. In most cases, this tendency will be balanced by the limiting viscosity change or by the increase of pump discharge pressure due to lowered rate of flow.

(*d*) In **critical processes**, the unbalancing tendency in (*c*) may be sufficient to overcome balancing factors. In the example under (*c*), an oil might possess great enough viscosity change with change of temperature to increase the resistance to flow faster than the balancing factors increase, resulting in complete stoppage of flow. Exothermic chemical reactions are frequently quite violent in their inherent unbalancing tendencies.

Process Lags

Process lags may be defined as the "retardation or delay in the value or condition of a process variable with respect to the immediate condition of another variable to which it is closely related." (Mason, "Quantitative Analysis of Process Lags," *Trans. A.S.M.E.* May, 1938.) These lags result from combinations of energy-storage capacities and energy-flow resistances in the process. They are of three forms: **Capacity lag** results from the ability of a process to store up energy; relatively large amounts in that part of the process being controlled are generally helpful to automatic control. **Transfer lag** results from the resistance offered to the flow of energy between two or more capacities; it is generally an unfavorable factor and is not dimensionally expressible, since it involves complicated functions of time. **Distance-velocity lag** results from any physical or mechanical characteristic of the process that requires time for the effect of an instantaneous change in a variable to be carried to that part of the process where it may affect the controlled variable; it is also generally an unfavorable factor.

Under balanced operating conditions, there is no analyzable necessity for automatic control. It is only under changing conditions that it becomes necessary. The function of automatic control is to restore balance; but the manner in which it successfully accomplishes this must take into account the reaction of the process to the restorative action. The reaction of the process will depend upon its lag characteristics, which are transient phenomena.

In a-c automatic welding for high-grade pressure vessels with shielded-arc electrodes the deposit per pass is about 1/8 in. The weld bottom of the groove is usually chipped out and rewelded from the back.

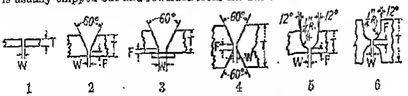

Fig. 2.—Proportions of Metal Arc Weld Grooves.

The dimensions in inches represented by the letters in Fig. 2 are as follows:

Groove	1	2	3	4	5	6
T	1/8–3/16	1/4 up	1/2 up	1/2 up	3/4 up	3/4 up
W	0–1/16	0–3/16	3/16–1/4	0–3/16	0–1/16	0–1/16
F	....	0–1/16	0–1/16	0–1/16	1/8 ± 1/32	1/8 ± 1/32

Table 2. Welding Speed. Atomic-hydrogen Hand Welding

Plate thickness, in.	Welding speed, in. per min			
	Lap and fillet	Butt	Corner	Edge
1/32		8–9	11–12	11–13
1/16	8–9	9–12	13–14	12–13
3/32	7½–8½	8–10	10–11	10–12
1/8	7–8	7–10	9½–10	9–10
5/32	5–6	5–7	6½–8	7½–9
3/16	3½–4½	3–3½	4–5	5½–6
1/4	2½–3½	2½–3	3–3½	4–4½
5/16	2–3	1½–2½	2½–3	3–4
3/8	2–2½	1–1½	2–3	2½–3½
1/2	1½–2	3/4–1	1½–2	2–2½

With 100 (125) [150] amp welding current the metal deposited per hour is 6–9 (7–8) [8–10] cu in.

Table 3. Physical Properties of Shielded and Unshielded Weld Metals

Physical properties	Base metal	Weld metal	
		Deposited with a metallic shielded arc electrode	Deposited with a metallic bare electrode
Tensile strength, lb per sq in.	55,000–70,000	60,000–75,000	50,000–60,000
Yield point, lb per sq in.	30,000–32,000	45,000–60,000	38,000–45,000
Elongation, % in 2 in.	30–40	20–40	5–10
Elongation, free bend, %	—	35–60	10–20
Reduction in area, %	60–70	35–65	8–20
Density, g per cc	7.85	7.80–7.85	7.50–7.70
Endurance limit, lb per sq in.	26,000–30,000	26,000–30,000	12,000–18,000
Impact, Izod, ft-lb	50–60	40–70	5–15

MODES OF OPERATION

Automatic control action can be divided into (A) on-and-off (open-and-shut) which produces maximum or zero value of the adjusted flow, with no intermediate quantities, and (B) throttling which may mean either proportional control (see definition below) or any type of control action intended to produce values of adjusted flow intermediate between zero and maximum. In this discussion, it will be used in the latter sense.

(A) **On-and-off control** produces a distinct and sudden change of adjusted flow and for many applications has a distinct advantage. The greater and more nearly instantaneous the correction following a disturbance, the sooner the value of the variable will recross the set point. Hence, it is more competent to deal with widely varying and upsetting conditions than are throttling types.

A(1) In its simplest form, an on-and-off controller moves its final control element completely through its stroke upon the minimum possible deviation of the controlled variable from the set point. This is referred to as **fast open-and-shut** action, or zero dead zone. Where process conditions require on-and-off action, it is essential that the dead zone be as nearly zero as can be obtained, in order to minimize the magnitude and period of the permanent cycle.

A(2) A variation of A(1) is frequently used to minimize mechanical wear of the final control element or to improve combustion efficiency, as in the case of domestic thermostats. In this case, the final control element is operated in one direction at one value of the controlled variable and is not operated in the opposite direction until the correction resulting from its action has brought the controlled variable back across a dead zone to another value. This dead zone or **differential gap** produces a definite cycle in the control, which frequently is larger than the amount of the differential, especially in the presence of velocity distance or transfer lag. Various **anticipators** are used to overcome this overrun, but, in general, they are successful only when carefully adjusted for a narrow range of load variation. The differential gap type of on-and-off control is one of the most widely used automatic controllers and is found in practically all domestic thermostats.

(B) The essential feature of **throttling control** is that the flow of the control agent is continuous. It simulates hand control and is frequently considered to be a superior type. The mechanism is generally more complicated and expensive than that of the on-and-off type. Each type fulfills a definite function, and the selection of either should be based on the requirements of the application.

Types of Throttling Control. B(1) **Limited on-and-off** (two-position) control mechanically is a variation of A(1) and A(2), obtained by limiting the stroke of the final control element or by restricting its effect upon the adjusted flow by by-passing part of the flow of control agent around the final control element. It has been most highly developed in electrically operated controllers, which are more difficult to make of throttling type than are those pneumatically operated. Where capacity lag is preponderant, and load range is small, it is very effective.

B(2) **Two-position with rate control** is a modification of on-and-off control of the differential gap type, wherein the action of the final control element is slowed down so that it is not able to complete its stroke during the over- or under-run period. There is no correspondence between the value of the controlled variable and the position of the final control element. As long as the value of the variable is outside the dead zone, the final control

Design Strengths

The bridge specifications of the A.W.S. (1940) permit design stresses in properly made butt joints, welded from both sides, of 13,500 lb per sq in. when the service stresses vary from zero to a maximum. When the service stresses are completely reversed, only 9,000 lb per sq in. is allowed. There is a penalty of 15 percent in allowed stress in case of single-V backed-up welds. In butt welds subjected to a pulsating shear varying from zero to a maximum a design value of 9,000 lb per sq in. is allowed. This is reduced to 6,000 lb if the shearing stress is completely reversed. The same 15 percent penalty applies to single-V backed-up welds.

Fillet welds subjected to tension, compression, or shear are allowed 7,200 lb per sq in. stress when the stress varies from zero to a maximum and 4,800 lb when the stress is completely reversed. Only a good grade of heavily covered electrods is permitted in bridgework.

The building code of the A.W.S. requires that welded joints shall be proportioned so that the stresses caused therein by loads specified in the Building Code shall not exceed the following values, expressed in thousands of pounds per square inch:

Kind of stress	For welds made with filler metal	
	Shielded arc	Bare or lightly coated
Shear on section through weld throat	13.6	11.3
Tension on section through weld throat	15.6	13.0
Compression (crushing) on section through throat of butt weld	18.0	18.0

Fiber stresses due to bending shall not exceed the values prescribed above for tension and compression, respectively. Stress in a fillet weld shall be considered as shear, for any direction of the applied stress. In designing welded joints, adequate provision shall be made for bending stresses due to eccentricity, if any, in the disposition or sections of base-metal parts.

Gas Welding

Gas welding is fusion welding in which heat is supplied by burning a mixture of oxygen and a suitable combustible gas. The gases are mixed in a blowpipo or torch which gives complete control of the welding flame.

Acetylene is almost universally used as the combustiblo gas because of its high flame temperature. This temperature, estimated to be about 6000 F, is so far above the melting point of all commercial metals that it provides a means for the rapid localized melting essential in welding. The oxyacetyleno flame is also used in cutting ferrous metals.

The **oxyhydrogen** flame is used in welding metals that have low melting points, such as lead, and in welding thin aluminum sheet.

It is essential that the weld should penetrate entirely through the metal. Beveled edges forming a V should be used where the thickness of the metal is such that it would be difficult to secure this penetration with butted edges. To build the weld up to the original surface, welding rods must be used to fill up the V.

Bronze Welding. (Braze Welding.) It is sometimes possible to produce sound strong joints in metals without actually melting the base metal. Thus in bronze welding the edges of the joint are heated to a dull red heat by oxy-acetylene. With the base metal at the proper temperature and with the aid of a suitable flux, molten bronze from a bronze welding rod will unite with the

element continues to move. This type of control is used to some extent where the process-lag characteristics are favorable but is relatively limited in its application.

B(3) In **variable rate of integrating control,** the rate mechanism of B(2) is supplemented by an effect that increases the speed of action of the final control element in proportion to the amount of deviation of the value of the variable from the set point. Independently, it has very little application, except in some simple pressure-regulation applications, but is combined with other types in widely used commercial controllers.

B(4) In the dynamic consideration of **proportional control,** the controlling means is caused to vary in proportion to variations of the measured variable, within a range known as the **proportioning band** (also called throttling range). Statically, the deviation of the controlling means from its midvalue is proportional to the deviation of the variable from midposition of the proportioning band. In all dynamic behavior, the proportionality is maintained regardless of the behavior of the measured variable, as long as it is within the proportioning band. The rate of change of the variable produces proportionate rates of change of the controlling means. This proportionality holds for all derivatives. It is a simulation of the self-regulation of the process itself, and where positive self-regulation is already present in the process, may be thought of as making it more effective; or where it is not present, may be thought of as furnishing it. This type is widely used; the common pressure-regulator or reducing valve falls within this classification.

B(5) **Multipositional Control.** Many ingenious mechanisms and electrical circuits have been developed to approximate proportional control by multiple-step action, with various combinations of B(2) and B(3). Where such action is useful, equally good or better results may be secured by the use of true proportional control.

B(6) **Proportional Control with Automatic Reset.** Since proportional control must permit deviations of the value of the variable in order to institute corrective action, combinations of B(2) or B(3) with B(4) are used to secure its desirable throttling action without permanent deviation.

Control systems may be (1) by means of a group of more or less related but unconnected instruments used to control all pertinent variables of a process or (2) by the use of several controllers interconnected to produce a single end result. This interconnection may be (a) **multiple,** in which case a **master controller** varies the set points of several independent controllers simultaneously according to some preestablished relation, as in several boiler combustion-control systems; or (b) **cascade,** in which type several controllers vary the set points of succeeding ones, in order to eliminate the effect of outside upsetting conditions and to make the control action of the first instrument in the cascade consistent in its effect. An example of this is a temperature controller varying the set point of a flow controller which varies the set point of the governor of a prime mover driving a pump, which is pumping the control agent.

(C) **Special Modes of Control.** C(1) **Relation Control.** It is frequently desired to keep the value of a variable in some direct relation to the value of another variable, although there is no reaction upon the second from the variation of the first.

Example. Control of relative humidity may be secured by suitably varying the set point of a wet-bulb controller according to variations in dry-bulb temperature. In "comfort cooling" of buildings, it is desirable to keep the indoor temperature only a

base metal to form a strong bond. A bronze weld is comparable in strength to a fusion weld.

With practically all the common metals except steel, it is necessary to use a suitable **flux**. The flux unites with the oxides to form an easily fusible slag. Special fluxes are necessary for fusion welding cast iron, for bronze welding, for fusion welding brass and bronze, for welding chromium alloys such as stainless steel, and for welding aluminum.

With a one to one mixture of oxygen and acetylene the resulting flame is **neutral**. The neutral flame has an inside portion consisting of a brilliant cone $\frac{1}{16}$ to $\frac{3}{4}$ in. long, surrounded by a faintly luminous envelope flame. When acetylene is in excess, the flame consists of three easily recognizable zones: a sharply defined inner cone, an intermediate cone of whitish color, and the bluish outer envelope. The length of the intermediate cone is a measure of the amount of excess acetylene. This flame is reducing, or carburizing.

When oxygen is in excess in the mixture, the flame resembles the neutral flame, but the inner cone is shorter, is "necked in" on the sides, is not as sharply defined, and acquires a purplish tinge. A slightly **oxidizing flame** is used in bronze welding and bronze surfacing, and a more strongly oxidizing flame is used in fusion welding brass and bronze.

By using a **carburizing** or excess acetylene **flame**, advantage can be taken of the facts (1) that hot steel readily absorbs carbon, (2) that high-carbon steel has a much lower melting point than low-carbon steel, (3) that carbon very effectively reduces iron oxide, and (4) that carbon disperses or migrates through hot steel at a rapid rate. Directing the flame backward over the completed weld but in such a way that the excess acetylene flame touches the scarf or V in advance of the welding puddle serves to reduce any iron oxide on the surface of the metal. The reduction of the oxide leaves a very porous spongy type of iron which very readily absorbs carbon from the flame, and the melting point falls as the carbon increases until, with fully carburized iron, it is nearly 700 F *below* the melting point of carbon-free iron. This procedure eliminates the gas-producing scale at a point in advance of the welding operation so that blowholes are prevented and adds carbon to the surface of the base metal. The carburized low melting-point surface of the scarf is easily brought to a sweating condition which is perfect for forming the union between the liquid metal from the rod and the base metal. There is no need for melting into the scarf to ensure the presence of clean metal for this union, and, as a result, the width of the groove need not be so great as in earlier methods; hence less rod must be melted to fill it, and this, together with the elimination of melting the scarf, leads to rapid easy welding at a reduced cost for welding materials. The carburized surface of the scarf is rapidly absorbed by the added metal, and the carbon is diffused uniformly through the weld while still at a high temperature, giving a uniform strong and ductile weld metal.

Machine Welding. Oxyacetylene welding by machines is applied in the manufacture of steel barrels, tubing, irrigation pipes, special forms, nickel and monel tubing. Multiple-flame water-cooled machine torches make welds at rates several times that possible by the most expert hand welders. Machine welding is done with and without welding wire, mostly *without*, on tubing and pipe, the welds being compressed in the process to make a flush or reinforced joint.

Gas Cutting

Gas cutting is employed for wrought iron, steel, and cast iron. The tips of the torch are usually made with a central orifice for the oxyacetylene cutting jet, around which are disposed several smaller orifices for the preheating flames. The latter are produced by burning mixed oxygen and acetylene, or fuel gas. Their function is heating the iron to the kindling temperature, 1500 F. The **oxygen cutting jet** burns the iron in its path,

certain amount below outdoor temperature to avoid undesirable shock to persons going outdoors. In chemical processes, it is frequently desirable to have a pressure or flow vary according to the variation in a temperature—or vice versa.

C(2) **Ratio Flow Control.** This is a special case of (1), in which the set point of a rate-of-flow controller is varied according to variations in the flow through another line; *e.g.*, varying the flow of an absorption oil according to the variations in flow of the gas from which it is absorbing a constituent, varying the rate of flow of air to sewage aerators in accordance with the rate of flow of raw sewage.

In some cases, the ratio between the two flows measured by a ratio-flow controller (the "primary" or uncontrolled flow and the "secondary" or controlled flow) is varied by another controller; *e.g.*, in some steam desuperheater applications, the velocity of steam and water is kept in ratio by a ratio-flow controller, with a temperature controller adjusting the ratio to secure the final exact temperature desired. This kind of combination is frequently desirable where load variations are abrupt and large and process lags are such as to prevent the possibility of quick action by the end-result controller. In such cases, the swings are taken care of approximately by the ratio-flow controller and exact adjustment under balanced operating conditions by the final controller. Where complicated process lags exist, even this setup may not produce good final results during transient conditions, since it does not take account of intermediate storages of energy and their transient influence.

C(3) **Averaging Control.** In many processes, it is desirable to keep upsets in one part from being passed on to another part. For this purpose, surge vessels are installed between them.

It is frequently desirable to control the storage in these chambers automatically, in such a way that the effect of a cycling or varying inlet flow to the vessel will be attenuated to the maximum possible extent, in order that the *average* change in flow rate will be passed along to the succeeding apparatus. This is a direct contradiction of the purpose of most automatic-control apparatus but is quite successfully handled by using a mechanism of the "proportional with reset" type, in which the proportion between variation of the value of the variable and corrective action is made relatively high (relatively wide throttling range) and the rate of reset is relatively slow.

The conditions should permit the actual outlet flow to be definitely and exactly responsive to the corrective action of the controlling means and not be affected by outside factors; when this is not possible, a "control system" should be used that will nullify outside effects also tending to influence the flow.

C(4) **Time or Program Control.** In many processes, operations require the gradual change of value of a variable according to a definite schedule. This may be secured by varying the set point of an automatic controller by means of a clock or motor-driven cam. In some cases, the cam setting is determined by the progress of the condition of the material being processed, rather than strictly according to time, in which case it might be said that each batch of material determines its own schedule.

Complicated process lags may prevent strict adherence to a time schedule, and where they exist, better over-all results may be secured by the use of time-flow (or other individual variable) controllers, rather than a time-schedule controller on the end-result variable, such as temperature.

C(5) **Combustion Control.** The requirements of boiler control include factors not ordinarily considered in the average industrial application. A discussion of its requirements will be found on p. 1160.

AUTOMATIC-CONTROL MECHANISMS

Friction, lost motion, and unbalance are the prime causes for trouble in automatic controllers. It is almost impossible to overemphasize this. In proportional controllers without automatic reset, the dead zone resulting

and as the torch is moved over the surface it makes a clean cut with narrow kerf comparable to that made with a metal saw.

The maximum thickness of metal that can be cut by high-temperature flames depends largely upon the gases used and the pressure of the oxygen. The thicker the material, the higher the pressure required. When using the oxyacetylene flame, it is possible to produce smooth cuts up to 10 in. or more in thickness. The oxyhydrogen flame will cut material up to 24 in. in thickness.

The torch-cutting process is widely used for fabricating steel plates and structural shapes, cutting field rivet holes, beveling for welding, cutting pipe to length and angle for welding, clearing away wrecks, scrapping old machinery and structures, cutting rivet heads and stay bolts, and removing plates from fireboxes.

Influence of Alloying Elements on Cutting. Alloying elements have two possible effects, they may increase the resistance of steel to cutting and they may give rise to harder cut surfaces. Where an alloy steel is difficult to cut by other means, an improvement is effected by tightly clamping a "waster" plate to the upper surface and cutting through both thicknesses. Another method is to weld a heavy bead on the upper surface along the proposed line of cut.

Steels up to 0.30 percent **carbon** can be cut without difficulty. Higher carbon steels should be preheated to about 600 F to prevent hardening. Graphite and cementite (Fe_3C) are detrimental, but cast irons containing 4 percent carbon may be cut by special technique.

Steels up to 14 percent **manganese** and 1.5 percent carbon are cut with difficulty and for best results should be preheated.

Silicon in amounts usually present has no effect. Silicon steel containing considerable amounts of carbon and manganese must be carefully preheated and postannealed for best physical properties.

Steels up to 5 percent **chromium** are cut without much difficulty when the surface is clean. Higher chromium steels, such as the 10 percent chromium steels, require special technique, and the cuts are rough. In general, carburizing preheating flames are desirable when cutting this type of steel.

Nickel up to 20 or 30 percent (if the carbon is not too high) may be cut. Up to about 7 percent nickel content, cuts are very satisfactory.

Aircraft quality chrome-**molybdenum** steel offers no difficulties. High molybdenum-tungsten steels, however, may be cut only by means of special technique.

Tungsten alloys up to 12 or 14 percent may be cut very readily, but with a higher percentage of tungsten cutting is difficult.

Vanadium in small amounts may improve cutting. The other common alloying elements have no appreciable influence.

Oxygen-cutting machines are capable of making oxygen cuts with jigsaw flexibility and of such high quality and accuracy as to require no further finishing. Cutting machines are frequently equipped with more than one cutting torch, centrally controlled and guided, and will oxygen cut a number of identical shapes simultaneously, thereby effecting marked economies where a high production rate prevails. Other machines will crawl around pipes, making one or two square or beveled cuts, as desired.

Oxyacetylene Cutting

Thickness, in....	¼	½	1	2	4	6	8	10

$= -\frac{1}{\sqrt{b^2-ac}}\tanh^{-1}\frac{b+cx}{\sqrt{b^2-ac}} + C,$

when $b^2 - ac > 0$;

24. $\int \frac{dx}{a+2bx+cx^2} = -\frac{1}{b+cx} + C,$ when $b^2 = ac$

25. $\int \frac{(m+nx)dx}{a+2bx+cx^2} = \frac{n}{2c}\log_e(a+2bx+cx^2) + \frac{mc-nb}{c}\int \frac{dx}{a+2bx+cx^2}$

26. In $\int \frac{f(x)dx}{a+2bx+cx^2}$, if $f(x)$ is a polynominal of higher than the first degree, divide by the denominator before integrating.

27. $\int \frac{dx}{(a+2bx+cx^2)^p} = \frac{1}{2(ac-b^2)(p-1)} \times \frac{b+cx}{(a+2bx+cx^2)^{p-1}}$

$+ \frac{(2p-3)c}{2(ac-b^2)(p-1)}\int \frac{dx}{(a+2bx+cx^2)^{p-1}}$

28. $\int \frac{(m+nx)dx}{(a+2bx+cx^2)^p} = -\frac{n}{2c(p-1)} \times \frac{1}{(a+2bx+cx^2)^{p-1}}$

$+ \frac{mc-nb}{c}\int \frac{dx}{(a+2bx+cx^2)^p}$

29. $\int x^{m-1}(a+bx)^n dx = \frac{x^{m-1}(a+bx)^{n+1}}{(m+n)b}$

$-\frac{(m-1)a}{(m+n)b}\int x^{m-2}(a+bx)^n dx$

$= \frac{x^m(a+bx)^n}{m+n} + \frac{na}{m+n}\int x^{m-1}(a+bx)^{n-1}dx$

IRRATIONAL FUNCTIONS

30. $\int \sqrt{a+bx}\,dx = \frac{2}{3b}\left(\sqrt{a+bx}\right)^3 + C$

31. $\int \frac{dx}{\sqrt{a+bx}} = \frac{2}{b}\sqrt{a+bx} + C$

32. $\int \frac{(m+nx)dx}{\sqrt{a+bx}} = \frac{2}{3b^2}(3mb - 2an + nbx)\sqrt{a+bx} + C$

33. $\int \frac{dx}{(m+nx)\sqrt{a+bx}}$; substitute $y = \sqrt{a+bx}$, and use 21 and 22

34. $\int \frac{f(x, \sqrt[n]{a+bx})}{F(x, \sqrt[n]{a+bx})}dx$; substitute $\sqrt[n]{a+bx} = y$

35. $\int \frac{dx}{\sqrt{a^2-x^2}} = \sin^{-1}\frac{x}{a} + C = -\cos^{-1}\frac{x}{a} + c$

36. $\int \frac{dx}{\sqrt{a^2+x^2}} = \log_e\left[x + \sqrt{a^2+x^2}\right] + C = \sinh^{-1}\frac{x}{a} + c$

37. $\int \frac{dx}{\sqrt{x^2-a^2}} = \log_e\left[x + \sqrt{x^2-a^2}\right] + C = \cosh^{-1}\frac{x}{a} + c$

38. $\int \frac{dx}{\sqrt{a+2bx+cx^2}} = \frac{1}{\sqrt{c}}\log_e\left[b + cx + \sqrt{c}\sqrt{a+2bx+cx^2}\right] + C,$ when $c > 0$;

$= \frac{1}{\sqrt{c}}\sinh^{-1}\frac{b+cx}{\sqrt{ac-b^2}} + C,$ when $ac - b^2 > 0$;

$= \frac{1}{\sqrt{c}}\cosh^{-1}\frac{b+cx}{\sqrt{b^2-ac}} + C,$ when $b^2 - ac > 0$;

$= \frac{-1}{\sqrt{-c}}\sin^{-1}\frac{b+cx}{\sqrt{b^2-ac}} + C,$ when $c < 0$

39. $\int \frac{(m+nx)dx}{\sqrt{a+2bx+cx^2}} = \frac{n}{c}\sqrt{a+2bx+cx^2} + \frac{mc-nb}{c}\int \frac{dx}{\sqrt{a+2bx+cx^2}}$

40. $\int \frac{x^m dx}{\sqrt{a+2bx+cx^2}} = \frac{x^{m-1}X}{mc} - \frac{(m-1)a}{mc}\int \frac{x^{m-2}\,dx}{X} - \frac{(2m-1)b}{mc}\int \frac{x^{m-1}\,dx}{X},$ where $X = \sqrt{a+2bx+cx^2}$

41. $\int \sqrt{a^2+x^2}\,dx = \frac{x}{2}\sqrt{a^2+x^2} + \frac{a^2}{2}\log_e\left(x + \sqrt{a^2+x^2}\right) + C$

$= \frac{x}{2}\sqrt{a^2+x^2} + \frac{a^2}{2}\sinh^{-1}\frac{x}{a} + c$

42. $\int \sqrt{a^2-x^2}\,dx = \frac{x}{2}\sqrt{a^2-x^2} + \frac{a^2}{2}\sin^{-1}\frac{x}{a} + C$

is an oxygen jet. Metals may be removed at a rate of 10 to 15 lb per min. The oxygen consumption with present practice amounts to approximately 3 cu ft per lb of steel removed.

Carbon-arc cutting depends upon melting, except where a combination of the carbon arc with oxygen gas is used for certain work. Space must be left under the plate for the molten metal and slag to run out of the cut. The carbon arc is used for burning holes in metals and for cutting rivets. Current may vary from 450 amp for light work to 1,200 amp for general and heavy cutting. The cut made by the carbon arc is not smooth, but for scrap work it may sometimes be used economically.

Cutting metals under water can be accomplished by the electric arc or the oxyacetylene flame. The arc method combines the heat of the electric arc with the oxidizing flame of a stream of oxygen.

The torch method consists essentially of an oxyacetylene cutting torch surrounded by a protecting bell through which is forced compressed gas. Special methods are used to permit the lighting of the torch underwater.

Resistance Welding

In resistance welding (**Thomson process**) the parts to be joined, after proper shaping, are pressed together (Fig. 3). A large current is then passed through the joint until it has reached welding temperature. The current is

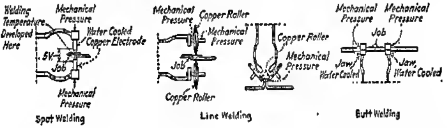

FIG. 3.—Diagrams of Circuits of Butt, Spot, and Seam Welding Machines.

stopped and further pressure, if needed, is applied, upsetting the joint and completing the weld.

As the electrical resistance of the contact surface is much greater than that of the solid metal, most of the heat is generated at the joint surface. *The larger the current, the more rapid the heating, the less the heat extends* back from the joint into the metal, and the less the upset.

The voltage required is so low and the current so high that the only convenient source is an a-c transformer built into the welder and as close as possible to the jaws which hold the parts and transmit the current to them. To conduct these heavy currents from any considerable distance involves either an excessive amount of copper or an excessive loss of power. Resistance welding is particularly adapted to production work, and special-purpose welders are used for large production.

Resistance welding is applied to most non-ferrous as well as to ferrous metal parts. For work of any considerable size, these machines are not readily portable, *i.e.*, the work must ordinarily be brought to the machine.

The type of resistance welding described above is the original form, known as **butt welding**, and has been applied to joint sections up to 36 sq in. in section.

With **non-ferrous** metals, with some exceptions such as platinum, the period of plasticity is short, and consequently a hand-operated pressure

If the temperature of the base metal in bronze welding is too low, the bronze does not spread out; if it is too high, the bronze collects in little balls which are driven away by the force of the flame. To avoid overheating, the torch should be held at a smaller angle to the deposited metal than in welding. Bronze welding of large joints should be done in several layers. The removal of graphite from the surfaces to be welded is important. Graphite may be removed by sealing the surface at 1650 F or by use of an oxidizing flame. A slightly oxidizing flame is usually recommended.

The flux should be oxidizing in character in order to remove graphite, and it should remove oxide films from the base metal, otherwise capillary flow of the bronze (tinning) will not occur without overheating. The customary filler rod for bronze welding is a brass containing 60 Cu, 40 Zn. If the zinc content is too low, the hot strength is correspondingly low; if zinc is too high, the deposited metal is too hard and brittle. Tin, iron, manganese, and silicon, about 1 percent, are often added to improve the flowing characteristics, decrease fumes, deoxidize, and increase the hardness. The V need be only wide enough so that the torch can be inserted. Double V joints are used for thick sections. In pipe welding the shear V joint is recommended.

With non-ferrous electrodes having a high melting point, covered electrodes (reversed polarity, short arc) are always deposited on cold metal. Beads not longer than 2 in. are deposited and peened lightly. After every second layer the deposit is caulked. For gas welding, bare rods are used with preheat and refined powdered borax. The usual high-melting-point non-ferrous electrode for cast iron is monel metal coated with deoxidizer and flux. Micrographic study reveals no hard zones in arc welds with monel electrodes. Good monel welds in cast iron have a tensile strength of 25,000 lb per sq in.

Malleable Cast Iron

Since the physical properties are dependent on certain heat-treatments which it undergoes, the heat of fusion welding will permanently change the structure and physical properties unless the temperature is kept below 1400 F. Bronze welding is the usual method of repair. The method is the same as for gray cast iron. The edges to be welded are beveled to 90 deg and cleaned. The scarfs should not be ground; grinding brings graphite to the surface and makes tinning difficult. The casting is then preheated to a black heat (locally for small castings) and bronze welded, using a tip one size larger than for similar work on steel and an oxidizing flame. Flux is used liberally. The rod may contain 59 Cu, 40 Zn, or 1 Fe, plus some Mn; lead is bad. Other rods such as manganese bronze and Cu-Zn-Si high-strength brass have also been found to be successful.

If the casting may be reannealed, *i.e.*, malleableized after welding, either arc or gas welding may be used as in cast-iron welding. The tensile strength and elongation of good arc, gas, and resistance welds in malleable cast iron which have been malleableized after welding are approximately 90 percent of those of the original malleable cast iron.

Wrought Iron

In the oxyacetylene welding of wrought iron a puddle of molten metal is maintained at the point of application of the filler rod. The end of the rod is immersed in the puddle until sufficient metal has been deposited. Then the edges of the molten puddle are fused into the surrounding colder metal. The weld progresses by repetition of this procedure. The puddle should be disturbed as little as possible to permit the slag to rise from the molten metal. The greasy appearance of the edges, that is noticeable in welding, corresponds to a temperature of 2100 to 2200 F, the correct temperature for welding being 2700 to 2750 F, a little higher than for mild steel. The filler rod can be low-carbon steel or a high-test rod. A neutral flame is best.

In metal-arc welding, slightly slower welding speeds should be used than for mild steel of the same thickness. In this way the metal is kept fluid longer, and gases and slag are eliminated. It may be necessary to use a slightly lower current than for the same thickness of mild steel, especially in thin sections where burning through is possible. Excessive penetration into the face of the metal should be avoided. High-grade unalloyed low-carbon electrodes should be used, bare or coated.

Carbon-arc welding and resistance welding of wrought iron are the same as those of mild steel.

butt-welder is not so satisfactory as a welder having spring or weight pressure, the full amount of which is exerted throughout the entire heating and welding operation. As soon as the abutting ends reach the welding or plastic stage, the spring or weight pressure forces them together, completing the weld and automatically breaking the primary circuit. This method is rarely used on parts having a crosssection over 0.25 sq in.

Welding Two Pieces of Material of Different Cross Section or of *Different Analyses*. *The tendency of a piece having a smaller cross-sectional area to heat the faster is offset by varying the projection of parts, i.e.,* by making the projection of the part having the larger sectional area somewhat longer than that of the smaller. Sometimes this can also be accomplished by preheating the larger section by means of a bridge or a piece of copper making contact with the die gripping the smaller part, so that when the circuit is closed the current flows and heats the larger part only.

In the **flash method** of butt welding the parts to be welded are clamped in the dies of the welding machine, giving equal or nearly equal projections to both parts, and usually the primary circuit is closed and the ends of the parts are brought together slowly. When these ends actually touch each other, they will flash, *i.e.*, minute particles of molten metal will fly off; this flashing is continued until the entire faces of the abutting ends have reached a welding heat when rapid and heavy pressure is applied, forcing the ends together and completing the weld, at the same time opening the primary circuit. With flash welding the power and time consumption is less, and the personal equation of the operator enters to a less degree than in butt welding. Some difficulty is encountered in flashing parts having cross-sectional areas over 8 to 10 sq in., where the ratio of their cross-sectional dimensions is over 50: 1, or less than 4: 1, although by preheating the parts in the latter case, this difficulty is greatly minimized. Flash welds are made both with cold and with preheated parts.

Cold flash is used for parts of an area well within the limits of the designed capacity of the welding machine. **Preheated flash** is used in welding parts having sections of an area closely approaching the design capacity of the welding machine and also where the physical or thermal characteristics of the parts are widely divergent.

In **welding non-ferrous metals** the cold flash is used entirely. The projection of the parts should generally be two or three times as great as in the welding of low-carbon steel. Platinum and similar metals are exceptions.

Strength of Resistance-welded Parts. In small sheet thickness up to 1/16 in. the strength of the spot weld is approximately 90 percent of that of the original material. In heavier thicknesses, such as 1/4 in., the strength ranges from 60 to 80 percent provided that the proper welding conditions are being used.

Flash-welded sections of ordinary structural steel will show 100 percent of the strength of the metal. In flash welding of steel, less current is required than in straight butt welding. *The voltage during the flashing period, however, is considerably higher. One* square inch cross section of iron or steel requires 30 kva for 10 sec. As the time required is inversely proportional to the power, if welded in 1 sec it will require 300 kva.

Great care must be exercised in butt welding of higher carbon steel. There is a danger of decarburization. Furthermore, heating should not be too sudden. Preheating to about 700 F outside of the machine is recommended. The pieces should be cooled slowly. Welds between low- and high-carbon steel can be readily made and possess high strength. *In welding of high-carbon steel*, higher pressures are necessary, for it does not flow so easily as low-carbon steel at welding heat.

Spot Welding. Where air-tightness is not required, a lap seam may be welded in spots by clamping the seam overlap between two (usually round)

Nickel Alloys

Gas Welding. The oxyacetylene flame used should be very slightly reducing with only a slight feather no longer than ⅛ in. showing beyond the tip of the luminous cone. The end of the welding rod should be kept well within the flame, so as to prevent its oxidation. Besides being reducing, the flame should be soft, rather than harsh, as is the case when too small a tip is used.

A flux is always used for monel (except for gas welding monel with the silicon monel gas-welding rod for pickling service), but none should be used with pure nickel. A flux recommended by manufacturers should be used. The silicon monel gas-welding rod requiring no gas-welding flux was developed particularly for the welding of equipment exposed to sulphuric acid service and specifically for monel pickling equipment for the pickling of steel.

After painting the flux on both sides of the joint, then adjusting the flame to slightly reducing conditions, and after beginning to weld, monel flows freely. Nickel, which is not fluxed, flows a little sluggishly. The appearance of properly made gas welds is quite similar to that of good steel welds. For the best results on high-nickel materials there should be little puddling; the molten pool should be kept quiet, with the tip of the luminous flame just touching its surface.

Welding rods are of the same composition as the alloy being welded if uniform corrosion resistance, with lack of galvanic effects, is desired. Some leeway is possible with the deoxidizing additions. The manufacturers of nickel furnish proper welding rods where these are specified. Wire should be bright annealed and free from oxide. Only wires tested for their weldability should be used for monel or nickel welding.

Electric Welding. Heavily extrusion-coated rods are used for monel and nickel metallic-arc welding. As the presence of aluminum is desirable in or near the molten pool of monel-weld metal, a small amount of aluminum is included in the monel-core wire. The use of a slightly alloyed monel rod results in developing strengths of 70,000 to 80,000 lb per sq in. in single-bead and multiple-bead butt joints, metallic-arc welded in flat, vertical, or overhead positions. This is the range of tensile strengths obtained in plate material. It is possible to get still higher values by using a core wire of type K monel. Monel and nickel electrodes carrying relatively thick flux coatings require reversed polarity, as do most of the high-strength steel electrodes.

In the metallic-arc welding of sheets of light to medium gage between 0.037 and 0.125 in. thick, it is desirable to clamp the sheets to restrain buckling. For lighter gages, it has been found that beads made without weaving are entirely satisfactory. Electrode sizes of $\frac{3}{32}$ (⅛)[$\frac{5}{32}$] in. with 50 to 70 (70 to 80) [80 to 140] amp are used for 12(9) [< 9] gage sheets.

Carbon-arc welding is frequently applied to monel and nickel sheet in the intermediate range of gages of 0.037, 0.050, and 0.062 in., and heavier.

The length of the arc is maintained between $\frac{1}{16}$ and ⅛ in., a relatively short arc when compared with the long one required for copper carbon-arc welding.

Aluminum and Aluminum Alloys

Gas Welding. The commonly used gas processes for welding aluminum and aluminum alloys are oxyhydrogen and oxyacetylene. A suitable flux should be used to remove the oxide coating that forms on the surface of aluminum alloys in the atmosphere. The flux is applied either dry or by mixing with tap water to the consistency of a thick paste. Practically all aluminum welding fluxes contain chlorides, fluorides, and sulphates. Residual deposits on the joints after welding will, in the presence of moisture, attack the base metal. Thorough cleaning is necessary. Commercially pure aluminum and metal of higher purity are generally welded with the same grade of metal as the parent material. The same practice is satisfactory for the aluminum-manganese alloy. In welding the aluminum-magnesium alloys or the aluminum-silicon-magnesium alloys, a filler rod containing approximately 95 percent Al and 5 percent Si is generally used. This rod has a substantially lower melting point than pure aluminum and permits the dissipation of some of the stress set up by solidification shrinkage and the thermal contraction that occurs in the weld zone as it cools. Cracks in the weld and the transition zone, on parts that are welded in jigs to hold proper alignment, can be minimized by using this rod.

electrodes and passing the necessary current between them and through the overlapping edges of the plates (Fig. 3). As the electrical resistance of the surface contact is least in the region under pressure, most of the current is confined to a spot of about the same area as that of the electrodes. For relatively thin metal this method is more rapid and economical than other methods of making a joint where mechanical strength alone is required. With a double row of staggered spots the joint strength may be made equal to that of the sheets themselves.

In thin metalwork of such shape and size that it is inconvenient to bring the work to a spot welder, the overlap is laid against a heavy flat electrode and the other electrode at the end of a flexible cable is pressed against the joint by hand. For the spot welding of heavy plates (½ in. and over) the currents and pressures are very large, and considerable heat is developed at the surfaces of contact between the electrodes and the plates. The electrodes must have high thermal as well as electrical conductivity. The combination of high pressure and temperature at the electrode surfaces makes it necessary to reshape them frequently. Three 1 in. plates have been successfully spot welded, although the operation cannot as yet be considered a commercially successful one.

The depth of the throat of a welding machine is determined by the width of the plates to be welded. With a single-spot welder, the alternating current must be carried around the throat, linking the long steel plate, with its high magnetic permeability. The resulting high reactance of this circuit requires a higher voltage than the weld itself, makes necessary a transformer of large capacity, and produces a load of low power factor. This obstacle can be largely surmounted by having two electrodes on each side of the overlap and welding two spots at once (Fig. 4). The transformer can be located close to the electrodes either below or above, or both, and the current passed up through one pair of electrodes and down through the other. The two spots should not be very close together, or too large a part of the current would be shunted through the plate on the transformer side. In any case a considerable amount is so shunted, resulting in waste of energy and undesirable heating of the plate. Where a short throat suffices, the single spot machine is preferable. Another method employs two transformers, one below and one above, where two spots are made at once.

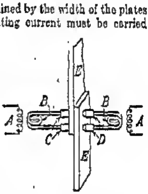

Fig. 4.—Wiring Diagram of Duplex Spot Welder.

Shot welding is a trade name applied to very rapid carefully-controlled spot welding of stainless steel.

In **projection welding**, projections are made on one or both of the work pieces and a flat die is used. This results in a smooth surface for the finished work.

Die points should have a diameter approximately equal to the total thickness of the two plates to be welded; the current used is about 50,000 amp per sq in. of die-point area; the pressure used is about 20,000 lb per sq in. of the die-point area. These figures will vary according to the stiffness of the plates, the distance between the welds, and the time required for making the welds.

In spot welding **high-carbon steel** it is desirable to employ a lower voltage than when welding the same thickness of stock of soft steel. The current is kept on for a longer time. Thin stock is easier to weld than heavier stock. Where slow welding is not permissible, it is desirable to heat-treat the welds.

As the aluminum alloys have a relatively high coefficient of thermal expansion compared with most weldable metals, it is desirable to minimize buckling and distortion from the welding heat by proper design and preparation of joints. Minimum distortion is obtained with edge or corner welds and in locations where the weld bead can be located on a crown or radius in the part at the weld. The location of welded seams or fittings in flat areas should be avoided.

Metal-arc Welding. Aluminum and the aluminum alloys can be fusion welded with the metallic arc. Because of the difficulty of controlling the arc it is not practical to butt weld material lighter than 0.081 in. thick in the shop or fillet weld joints on plate lighter than 1/8 in. thick. Electrode sizes are 1/8 (5/32) [3/16] in. with 45 to 85 (100 to 125) [175 to 225] amp and are used for <1/8 (1/8 to 1/4) [>1/4] in. sheets. Successful results are obtained by using a coated electrode on which a heavy coating is provided that functions both to remove the surface oxide on the metal and to stabilize the arc. As the 95 percent Al, 5 percent Si alloy provides superior fluidity at the welding temperatures, this alloy is used for the filler material in all the commercially available electrodes. No preliminary veeing is required on material up to 1/4 in. thick. Heavier materials should be veed to within 1/4 in. of the bottom of the section. Such preparation can sometimes be dispensed with on material 1/4 to 1/2 in. thick if a weld bead can be laid down from both sides of the section. In welding from one side only, it is desirable to confine the penetration bead by placing a metal backup strip below the joint. This strip should be provided with a cylindrical groove about 1/8 in. wide by 1/16 in. deep directly below the weld.

It is essential, if attack on the metal is to be prevented, to remove the residual welding flux on the joint after welding.

Electric-resistance Welding. The commercial aluminum alloys can be electric resistance welded. A machine should deliver at least 24,000 (35,000) [42,000] amp. to weld 1/16 (1/8) [3/16] in. thick material. A means of integrating the maximum current to permit the welding of intermediate thicknesses is also required. An autotransformer that will control the primary voltage from 20 percent full voltage to 100 percent voltage in 25 to 30 steps will provide adequate control of the current. For welding gages between 0.015 to 0.188 in. thick, periods varying from 2 to 25 cycles of the standard 60 cycle current wave are required. Good results can also be obtained on many types of work with contactor-type timers actuated either mechanically or by vacuum tubes.

For seam welding it is essential that full electronic equipment be used. The technique required involves delivery of the current to the work at a duty cycle of less than 30 percent. Timing cycles of 1 cycle on and 3 off, 1½ on and 4 off, or 2 on and 6 off are typical of the settings used for seam welding 0.032 to 0.064 in. material. Copper alloys with high electrical conductivity and mechanical strength have proved most satisfactory as tip materials. Water cooling to within 3/8 in. of the contact surface of the tips is necessary to ensure good tip life. It is necessary to clean only the area in contact with the welding tips, though, in a few cases, such as parts heat-treated in nitrate, it is desirable to clean one or both of the faying (contact) surfaces. It is also possible to clean the surface with an etching solution.

Aluminum alloys have low electrical resistance compared to ferrous alloys; currents ranging from 15,000 to 40,000 amp are necessary to cover the range of alloys and gages usually welded in an airplane factory. If these alloys are welded with high currents in short enough time it is possible to fuse the surfaces together without heating the outer surface or surrounding areas of the metal to an injurious temperature. Energy storage permits the development of the necessary high current without placing large maximum demand on the main lines. One type of equipment uses d-c power.

Resistance Butt Welding. Commercially pure aluminum, aluminum and 1.25 percent manganese alloy, and high-purity aluminum are readily electric butt welded and all the wrought alloys can be welded by this method.

The flash butt-weld process is adaptable to welding complicated extruded shapes of aluminum as well as the simpler cylindrical and rectangular shapes. Flashing is maintained for 1/2 to 1½ sec during which time 1/8 to 1 in. of aluminum is flashed from the parts being welded. The flashing period is terminated by the nearly simultaneous cutting off of power and a sudden increase in velocity of the moving die. The ends of

Special spot-welding electrodes are now used of a mixture of copper and special alloys such as tungsten, beryllium, and cadmium, the copper giving conductivity and the alloys rigidity and longer wear. A later practice uses chromium-plated copper electrodes.

In **seam welding** the overlapping edges of sheet metal are passed between two narrow roller electrodes (Fig. 3), the speed, current, and pressure being so adjusted as to produce a continuous seam weld by making a series of overlapping and closely-spaced spots. This method is limited to relatively thin sheets and is applicable to either straight or circular seams. It is employed in the manufacture of barrels, moderate-sized transformer tanks, and similar containers.

Tube Welding. Steel tubing may be made by the resistance welding of the edges of steel strip rolled up to form a tube. A single machine will take the flat strip, shape and weld it at a rate of 60 to 150 fpm. At these high speeds the fusion is confined to a thin surface layer, and the flash or upset is hardly perceptible. With alternating current of standard frequency (60 cycles per sec), high speeds result in an intermittent weld, for the heat is proportional to the square of the current and varies from zero to a maximum and back to zero, during each half cycle. This gives the appearance of a stitch on the outside of the tube, hence the common name of **stitch weld.** At a speed of 120 fpm (and 60 cycles) the stitches would be ½ in. apart. With a somewhat slower speed or higher frequency of current supply, the weld can be made continuous and airtight. No other process of tube manufacture can compete with this on the basis of cost. This process is at present confined to relatively thin-walled tubes. If the wall is thick as compared with the diameter, a relatively large amount of the current is shunted around the tube wall from the electrode rolls on either side of the seam.

Seam Welding

Total thickness, in.	0.016	0.032	0.059	0.098	0.157	0.197
Sec per ft of weld	9	15	22	33	45	55
Kva needed	6	8	12	16	25	30

The **current and energy required** in making welds can be varied over a wide range. In welding 1 sq in. of steel by the flash method the energy requirement may run from 30 to 350 kva, the voltage varying with these changes of current values. The average in such work may be 30 to 40 kw per sq in., or a total of 60 kw fed to the primary of the transformer. The power factor in such a case would probably not exceed 70 percent. The variables are many: the speed of work, the pressure applied, the current, the resistance of the piece, the heat conduction, the length of projection from the clamps, and the material of the clamps and their condition.

The optimum conditions for spot welding mild steel sheets 0.029 to 0.036 in. thick are a pressure of 15,000 lb per sq in. and exposure for 6 to 12 cycles with 12,000 to 13,500 amp for 60-cycle current and with electrodes ¼ in. diam. For stainless steel sheets 0.028 in. thick, the pressure is 50,000 lb per sq in. and the welding time 10 cycles or less with 9,000 amp.

Pulsation welding is a resistance welding method in which the welding current or heat is applied repeatedly for making a single weld, or simultaneous welds, in parts which are clamped between electrodes at rest. This is used when a single impulse of the same current is not sufficient to produce the weld.

The advantages of pulsation spot and projection welding are increased electrode life, the welding of thicker material with given equipment, and the production of better welds of improved appearance.

the parts being welded are forced together and rapid freezing of the weld takes place because of conduction of heat to the dies.

Characteristics of Welds in the Aluminum Alloys. When commercially pure and high-purity aluminum or the alloy with ¼ percent Mg are fusion welded, the welding heat removes the cold work in an area about two to four times the thickness of the section at the weld. *The tensile strength across a butt weld is not greater than the annealed* strength of the material regardless of the temper welded. Welds in this material are characterized by excellent ductility and a resistance to corrosion approximately the same as that of the parent material. An aluminum-magnesium-silicon-chromium alloy and an aluminum-silicon-magnesium alloy are used extensively in welded construction. In this case the welding heat partly obliterates the heat-treated structure, and the strength of the welds is intermediate between the annealed and heat-treated strength of the alloy.

Copper Alloys

For the welding of copper alloys, no general instructions are useful. Manufacturer's instructions should be sought or the A.W.S. Handbook consulted. See p. 629

Table 4. Data for Welding Fairly Clean Sheet Steel Stock
(Approximate)

SPOT WELDING

U. S. Standard gage No.	26	24	20	18	16	14	12	1/8"
Thickness, in.	0.0156	0.0250	0.0375	0.050	0.0625	0.0781	0.1094	0.125
Kw required	12	16	17	18	20	30	40	60
Time, sec	0.5	0.5	0.7	0.8	0.9	1.0	1.0	1.0

SLOW BUTT WELDING

Diameter, in.	1/4	3/8	1/2	5/8	3/4	1	1 1/4	1 1/2	1 3/4	2
Kw required	2.0	4	6	8	10	12	19	31	45	60
Time, sec	3	6	7	8	10	18	25	35	40	45

FLASH WELDING

Area of stock, sq in.	0.50	0.75	1.00	1.25	1.75	2.00	3.00	4.00
Kw required	25	30	60	80	200	250	350	500
Push-up pressure, lb.	800	1,750	3,150	5,000	9,600	12,500	35,000	60,000

These values will approximately hold for work where the greatest dimension of the welded section is not more than 4 in.

The following tabulation gives some examples of conditions for producing pulsation spot welds with 60-cycle current and clean surfaces.

Material	Tip diam, in.	Pressure, lb	Amp	Cycles		No. of pulsations
				On	Off	
Sheet steel, 1/8 to 1/8 in.	3/8	430	16,000	4	2	8
Steel bars, 1/4 × 2 in.	3/4	2,600	37,000	5	5	10
Steel bars, 1 × 3 in.	1	11,500	73,000	20	50	4 × 8
19 stacked steel sheets, 1/8 in. thick	3/4	3,300	58,000	13	31	5

Refrigeration Machines and Processes

(For general theory of refrigeration, see p. 349)

Refrigeration may be produced (1) through the absorption of heat by a gas that has been cooled by an expansion during which external work is performed, as in the air refrigerating machine; (2) through transferring heat by means of chemical machines or from a warmer body to a colder one (*e.g.*, refrigeration by cooled brine, water, etc.); (3) by melting or dissolving solid bodies, as in the melting of ice, the solution of salts in water and in chemical machines; (4) by evaporating liquids that have a relatively low boiling point temperature, as liquid ammonia and liquid carbon dioxide. The last type is the commercial method at the present time.

Air Machines (for theory, see p. 349). Air refrigerating machines are practically obsolete, because of their bulk, inefficiency, and operating difficulties. The **coefficient of performance** (the ratio of the useful refrigeration to the work of compression, see p. 350) of air machines is less than unity as compared with 4 or 5 in vapor machines. Table 1 gives results of tests of several of these machines. The expansion of air occurs in an engine that is preferably on the same shaft as the air compressor. The presence of water vapor in the air causes snow to form on the valves of the expansion cylinder.

Table 1. Test Results on Cold-air Machines
(Linde, *Trans. A.S.M.E.*, 14, p. 1416)

	System		
	Bell-Coleman	Lightfoot	Haslam
Air pressure in receiver, lb per sq in. abs.	61.0	65.0	64.0
Temperature of air entering compression cylinders, deg F	65.5	62.0	
Temperature of air after expansion, deg F	− 52.6	− 82.0	− 85.0
Ihp in compression cylinder	124.5	43.1	346.4
Ihp in expansion cylinder	58.5	28.0	176.2
Ihp in steam cylinder	84.4	24.6	332.7
Btu abstracted per hour per ihp of steam cylinder, at 20 F	668.0	1554.0	954.0

Chemical Machines. In most of these, the temperatures of water and brine are successively lowered by dissolving a salt (usually nitrate of ammonia) in water, the salt being recovered later by evaporating the water. They have no commercial importance.

Dry ice (solid CO_2) is useful as a refrigerating medium in special cases where the lack of drip is an advantage. The main objection to the general use of dry ice is its cost but

Aluminothermic (Thermit) Welding

Thermit is a trade name for a mixture of finely divided aluminum and iron oxide, which, upon reaction, produces one-half its weight of superheated molten steel and a molten alumina slag, both at a temperature of almost 5000 F. To this basic mixture are added oxides of other elements than iron, and in this way the analysis of the steel and its physical properties are controlled.

Thermit is an inert mixture until it is heated almost to the temperature of molten steel. A local heating initiates the reaction which then propagates rapidly through the mass of thermit and makes it possible to produce the desired amount of superheated molten steel in less than a minute.

The reaction is

$$3Fe_3O_4 + 8Al = 4Al_2O_3 + 9Fe$$

There are four varieties of thermit produced for the purpose of welding ferrous metals, *viz.*, plain thermit, cast-iron thermit, forging thermit, and wabbler thermit.

Plain thermit is used in making pipe welds where the material is used as a heating agent to bring the pipe ends to a welding temperature after which they are pressed together to form a pressure weld. **Forging thermit** *contains additions of nickel, manganese, and mild steel punchings to the* extent of about 17 percent and is used in the welding of all-steel sections. **Cast-iron thermit** has an addition of 3 percent ferrosilicon and 20 percent, mild-steel punchings and is used for the welding of cast-iron parts. **Wabbler thermit** is designed to produce a hard long-wearing, yet machinable, steel for building up worn wabbler ends of rolls and pinions.

In making a thermit weld the parts to be united are lined up and a space cut between these parts at the fracture. A wax pattern is then formed between and around the ends to be united, the wax forming a slight collar. The size of the gap and the dimensions of this collar are fixed by experience. The collar is not for the purpose of reinforcement, but rather to provide sufficient heat for the thorough fusion of the parts. A sand and clay mold is next rammed around the wax pattern and inside of a sheet-iron mold box, provision being made in the mold for heating gates and pouring gates and risers, the latter being placed at the highest points of the wax pattern and the others entering at the lowest points.

Figure 7 shows a longitudinal and a cross section of a typical mold. New molding material should be used next to the weld, gates, and risers, but previously used molding material may be used for backing.

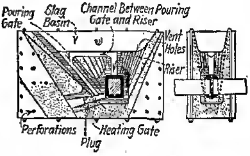

Fig. 7.—Mold for Making Thermit Welds.

Vent holes are provided in the mold to facilitate the escape of gases from the mold material. The parts are next heated to a bright red heat by means of a kerosine and air flame directed into the heating gate, which flame first melts out the wax and then while heating the parts to be welded also dries out the mold. In the meantime a suitable charge of thermit, which may be calculated from the weight of wax, is placed in a magnesite-lined crucible mounted over the pouring gate and when the preheating has been finished the heating gate is plugged and the thermit charge in the crucible ignited. In about 30 sec the reaction is

the ease in its handling, its low temperature of −110 F at atmospheric pressure, its non-corrosive and non-toxic properties, its high latent heat, and the absence of liquid drip make it desirable. The heat absorbed per pound of solid CO_2 during sublimation is 250.7 (246.3) [233.9] Btu at −140 (−110) [−70] F corresponding to 3.18 (14.7) [74.8] lb per sq in. abs. *The specific heat of the gas at constant pressure is about 0.2.*

Carbon dioxide is obtained commercially either by fermentation or by burning. The gas is compressed, usually in three stages, and cooled to atmospheric temperature, thereby forming a liquid at 900 to 1,100 lb per sq in. abs; the liquid is then throttled to about 5.3 atm pressure. During throttling, part of the CO_2 solidifies and is compressed to form a dense ice. The fraction that returns to the vapor phase is recompressed.

Water ice and common salt are still used commercially, as in the cooling of refrigerator cars and in passenger trains.

Vaporization Machines. Ammonia, water vapor, sulphurous acid, carbonic acid, ethyl chloride, propane, and other fluids are employed. These machines are of three types: vacuum machines, absorption machines, and compression machines.

In **water-vapor** refrigerating machines, the compression of the vapor is accomplished either by use of multistage centrifugal compressors or by the use of steam-ejector nozzles. Such machines are confined to comfort cooling, the cooling of drinking water, the cooling of rubber during the rolling process of its manufacture, and other applications which demand temperatures in the evaporator of 35 to 50 F, corresponding to pressures of the water vapor of 0.10 to 0.18 lb per sq in. abs; liquefaction is usually at about 100 F (1 lb per sq. in. abs), and cooling tower condenser water is frequently used.

In the water-vapor refrigerating machine, the return water from the sprays, or coils, and the make-up water enter an *evaporator* through a *throttle* (**expansion**) valve and the consequent vaporization of part of the water abstracts heat from the unvaporized part. The resulting cold water is pumped to the spray chamber or the cooling coils. The compression of the water vapor by multistage centrifugal compressors is similar to that used in the compression system. When steam jets are used, the machine consists of steam-ejector nozzles, an entrainment or mixing chamber, a booster ejector, and the water-cooled surface condenser. The steam pressure at the nozzles is preferably 150 to 100 lb per sq in. abs, in which case the weight of steam used is 20 to 35 lb per ton of refrigeration per hour, depending on the temperature of the chilled water desired in the evaporator and the steam pressure used in the nozzles. The amount of water supplied to the condenser is greater than in other refrigerating designs and is approximately 6 gal per ton of refrigeration per min. This type of refrigerating machine is built in sizes from 25 to 100 tons, but machines of 250 tons capacity have been installed.

Vapor machines using fluids other than water are of the compression type, the absorption type (p. 1866), or the adsorption type (p. 1874). The compression cycle is discussed on p. 350.

Liquids Used in Vapor Refrigerating Machines. In recent years, a number of refrigerants have been developed some of which are non-toxic and non-inflammable. Many of these are known by trade names, of which the following are perhaps the most prominent.

Freon 11 (Carrene 2), CCl_3F, Trichloromonofluoromethane
Freon 12, CCl_2F_2, Dichlorodifluoromethane
Freon 21, $CHCl_2F$, Dichloromonofluoromethane
Freon 113, $C_2Cl_3F_3$, Trichlorotrifluoroethane
Freon 114, $C_2Cl_2F_4$, Dichlorotetrafluoroethane

complete, and the contents of the crucible are converted into a superheated thermit steel at the bottom and alumina slag at the top. The tapping pin at the bottom of the crucible is struck a sharp upward blow releasing the thermit steel so that it runs from the crucible through the pouring gate of the mold and completely surrounds the ends to be welded giving up its superheat to melt these parts and solidifying with them. The thermit reaction is started by means of a teaspoonful of ignition powder which can be ignited with a match or a hot rod and which in turn gives off sufficient heat to start the reaction. The molds are usually constructed so as to provide a basin on top; the molten alumina slag overflows into this basin.

The tensile strength of unworked and non-heat-treated thermit steel is about 70,000 lb per sq in. with an elongation of 20 to 25 percent in 2 in. Other thermit steels have tensile strengths of 55,000 lb per sq in. with 40 percent elongation, and others over 100,000 lb per sq in. with practically no elongation. Mixtures can be placed in the crucible which will produce alloy steels of any desired composition.

The thermit process has been approved by the American Bureau of Shipping, by Lloyd's Register of Shipping, and by the other rating bureaus for use in the repair of stern frames and other important sections of steamers.

Thermit welding is used principally in the repair of cast-iron or steel sections over 3 in. thick; for lighter sections it is more expensive than oxyacetylene or electric welding. It is also used for the building up of worn parts.

In the steel mill, thermit welding is used in the repair of table rolls, roll mill housings, blooming-engine parts, crankshafts, connecting rods, charging peels, etc. By the use of wabbler thermit the worn surfaces on the driving ends of rolls, pinions, and other parts can be built up and the metal so accurately added as to require no machining; such a surface is just barely machinable and is very resistant to wear. The welding of heavy cast-iron parts introduces no difficulty when the thermit process is used, except that the high carbon content of the cast iron produces a high carbon content in the thermit steel weld, which may make machining difficult. The weld has at least as great strength as the cast-iron part.

One of the largest uses for thermit welding is the joining of rail ends in paved streets. In the railroad shop, thermit is used for the welding of locomotive frames, guide yokes, driving wheel centers, and other heavy parts.

Facing or Surfacing by Welding

Facing or surfacing by welding is a process of comparatively recent development which consists of welding onto wearing parts a facing, edge, or point of hard metal exceptionally resistant to abrasion or a metal suitable for the particular purpose as, for example, bearing or corrosion resistance. By this method, metal surfaces which normally wear away rapidly in service are protected by a layer of special alloy possessing unusual wear resistance. The process can be applied with equal advantage to new parts before their use or to old worn parts. The most important economy derived from hard facing is due to prolonged life of the parts. Hard-faced parts will outwear plain or unfaced ones 2 to 25 times, depending on the type of hard metal used and the service to which they are subjected. To meet the various requirements of hardness, toughness, shock-resistance, and other qualities, various hard-facing alloys of widely different compositions have been developed.

Most of the metals in common use except high-speed steels can be hard faced. Some metals and alloys require preheating or annealing, but generally the same precautions are followed as in the welding of these materials.

Silver Soldering

The term "silver solder" designates a type of hard solder or brazing alloy usually containing silver, copper, and zinc. Other base metals such as cadmium, tin, manganese, and nickel are also used. An important characteristic is the low melting point which is approximately 1160 to 1600 F, depending upon the composition. See p. 649.

[a] Values may be in error by a small amount.

Silver solders are free flowing, corrosion resistant, and produce strong joints that withstand severe shocks and vibration if used at ordinary temperatures. They can be used for joining practically all ferrous and non-ferrous metals and alloys except those having lower melting points, such as aluminum and zinc alloys.

WELDING PROCEDURES

Steel

Medium-carbon Steels. (Carbon from 0.30 to 0.45 by ladle test.) This class of steel may be welded by the electric-arc, electric-resistance, gas, and thermit processes. As the rapid cooling of the metal in the welded zone produces a harder martensitic or troostitic structure, it is desirable to hold the carbon as near 0.30 percent as possible. These hard areas are proportionately more brittle and difficult to machine. The cooling rate may be diminished and hardness decreased by preheating the metal to be welded to over 300 F, preferably to 500 F. The degree of preheating depends somewhat on the thickness of the section. Subsequent heating of the welded zone to 1100 to 1200 F will restore ductility and relieve strain.

High-carbon Steels. (Carbon from 0.45 to 0.80 by ladle test.) These steels are rarely welded except in special cases and in thick sections. The tendency for the metal heated above the critical range to become brittle is more pronounced than with lower or medium-carbon steel. Thorough preheating of metal in and near the welded zone to at least 500 F is essential. Subsequent annealing at 1350 to 1450 F is also desirable.

Low-alloy Steels. Those steels which are foolproof from the welding standpoint contain less than 0.15 per cent carbon. Steels containing less than 0.30 percent carbon may require a stress-relieving or tempering treatment and when fillet welded will generally develop a very narrow zone of reduced ductility. Steels containing 0.30 percent carbon or more require stress relieving, unless very special conditions are involved. Preheating is generally beneficial. The welding technique does not differ from that used in the welding of plain carbon steel.

Chrome-nickel austenitic steels are excellent material for welding and under satisfactory welding conditions produce strong, tough, and reasonably ductile welds. Alloys containing less than 0.07 percent carbon can be safely welded without any subsequent heat-treatment. In case of gas welding, it is safer to accelerate the cooling by means of an air blast, particularly if heavy sections ($\frac{3}{16}$ in. and above) are being welded. Alloys containing 0.07 to 0.10 percent carbon can be arc welded provided that the structures welded will not be used for service where high corrosion resistance is required.

No arc or gas welding should be attempted on alloys containing more than 0.10 percent carbon unless the complete structure can be subsequently heat-treated and rapidly cooled in an air blast.

Addition of titanium, columbium, or some of the other rare metals raises the safe carbon content of chrome-nickel alloys and permits arc welding of steel containing more than 0.10 percent carbon. In general, enough titanium or columbium is added to permit safe welding with the carbon content present. Such "stabilized" steel is not entirely proof from dangerous carbide precipitation.

Unstabilized alloys containing more than 0.07 percent carbon can be generally spot or seam welded without impairing their corrosion-resisting properties, provided that the welding time is made very short. The maximum safe length of the welding time will vary inversely with the carbon content of the alloy and somewhat with the welding technique used. With alloys with 0.10 percent carbon no dangerous carbid precipitation will occur if the time of the application of the welding current does not exceed 0.20 sec. With alloys having a carbon content of around 0.15 percent this figure should be reduced to 0.15–0.10 sec. maximum. All welding will produce some carbide precipitation, and the line of demarkation between the alloys that can and cannot be welded is a compromise between the extent of the carbide precipitation and the severity of the corrosion attack to which he welded product will be subjected. Chrome steels must never be arc welded with an unshielded arc. Special heavily coated electrodes must be used. Atomic-hydrogen arc by virtue of its protective blanket of hydrogen is satisfactory, but bare rod or carbon arc must never be used. No welding should be attempted without first thoroughly cleaning the surfaces to be welded or plating over an area extending not less than 1 in. on every side of the weld. Flash welding is, in general, quite satisfactory

range (5 to 86 F) and for other stated ranges also. Piston displacements are with no clearance. The theoretical coefficients of performance (see p. 350) for the various conditions covered in the table are obtainable by dividing 4.72 by the table theoretical hp. Data on some of the refrigerants not covered in Table 2 are given in Table 3. The expansion is through a throttle or expansion valve. The higher the compression ratio, the greater will be the superheat and the greater the resulting unproductive work of compression. Use of an expansion valve in place of an expansion cylinder results in a loss of refrigerating effect as well as in a loss of work which might

as most of the fused metal produced by the arc of the flash which could be expected to contain chromium oxides and nitrates is squeezed out by the upsetting operation and the weld obtained is therefore fairly ductile. Because of the amount of heating involved the straight butt-welding process should be avoided.

Chromium Iron and Steels. Welding of the chromium irons and steels can be divided into two classes: (1) welding in which the filler metal deposited has essentially the same chemical analysis as the base material; (2) welding in which the filler metal deposited is dissimilar in analysis and characteristics to the base metal, the filler metal commonly employed being an austenitic chromium-nickel steel of the 18 percent chromium, 8 percent nickel type. An austenitic chromium-nickel filler metal is used for all welds that cannot be annealed, including field and repair welds, and a filler metal of the same analysis as the parent metal for welds that can be annealed. For operation at high temperatures the expansion of the material must be considered. In a straight welded seam 30 ft long, there will be approximately 1¼ in. difference in expansion between the austenitic filler metal and chromium iron-base metal when heated to 1000 F. Operation at high temperature will result in warpage or high stresses and under repeated heating and cooling may result in failure through fatigue. The maximum corrosion-resisting properties of the austenitic steels are best realized by a rapid cool from temperatures higher than 1800 F, with either the unstabilized or stabilized steels. Since filler metal of the same analysis as the parent metal exhibits equivalent corrosion-resisting properties to the base material when properly controlled, it is recommended for all heat-treated welds under 18 percent chromium.

Austenitic Manganese Steel. In welding this material, it is important to remember that it is intrinsically a high-carbon metal, containing about the same amount of that element as the tool steel used for lathe tools. In arc welding with nickel-manganese steel rod, reversed polarity should be used, *i.e.*, the rod should be the positive pole. A nickel-manganese steel rod with a suitable coating welds smoothly, the arc sputters hardly at all, and it is possible to move the end of the rod steadily along without puddling the pool of metal. Some of the coated rods of this metal are self-feeding; the arc once started, the rod can be laid flat upon the work and the arc will travel steadily up the rod, like a slow-burning fuse, laying down a sound deposit. The slag coating over the deposited metal should break off readily at a light blow of the hammer. Peening can be started almost immediately as each length of rod is used up, as in the use of the bare rod.

It is best to lay the beads of each layer at right angles to those of the layer below, or at least at as high an angle as is feasible. In laying on metal to rebuild worn surfaces this is generally easy to accomplish. In repairing cracked or broken castings, especially heavy ones, the high angle may not always be easy to secure.

The current recommended for nickel-manganese steel rod is as follows:

Electrode size, in.	⅛	5⁄32	3⁄16	¼
Amperes	75–100	100–150	150–175	175–225

For gas welding, a tip should be selected large enough to melt down the metal with a soft flame, in order to minimize bubbling of the metal. A neutral flame should be used. A carbonizing flame makes the metal flow more freely but its use should be avoided.

Cast Steel

In good grades of cast steel with a carbon content below 0.25 percent, welding procedures are approximately the same as for rolled steel. With a carbon content above 0.25 percent or with special alloy compositions, precautions are necessary and sometimes special procedures. Segregations of phosphorus and sulphur should be removed from areas to be welded. The problem of overcoming shrinkage in repair of castings requires special care. Strains or stress relieving, especially repair work, is desirable. In higher carbon and alloy steels full annealing may be necessary.

For arc welding, a high-grade heavy-coated electrode is essential. A tough, general-purpose electrode (arc) or filler rod (gas) is used for plain carbon castings, but filler metal of the same composition as the casting is used for alloy cast steel.

Multilayer welding, high currents, and peening should be employed for low-carbon castings. Low currents and small diameter electrodes (and, in some cases, preheating

otherwise be available for operating the compressor. The magnitudes of these losses vary with the different refrigerants, and they are particularly high with a fluid that is compressed near to its critical pressure, as with carbon dioxide.

For the properties of water vapor see Table 20, p. 328, Table 21, p. 333, and Table 1, p. 374; for ammonia Table 25, p. 338 and Table 26, p. 341; for

sulphur dioxide, Table 27, p. 342 and Table 28, p. 343; for carbon dioxide, Table 29, p. 344; for ethyl chloride and methyl chloride, Table 30, p. 344; for propane and butane, Table 4; for Freon 11 and Freon 12, Table 5; for dieline and Freon 21, Table 6; for Carrene 1, Table 7.

The volume of refrigerant to be handled is important with reciprocating compressors, as it determines the size of the compressor; but with centrifugal compression a large volume is not objectionable and may be a positive advantage for small units. A large compression ratio is undesirable in reciprocating compressors from the standpoint of clearance losses and may make the use of compound compression necessary.

and slow cooling) are necessary for high-carbon and special alloy castings. For gas welding, only large sections are preheated, locally or generally, to a bright red.

Cast Iron

Gas Welding. Preheating in gas-welding cast iron avoids shrinkage stresses, cracks at the junction zone, and hard zone next to the weld and saves gases. Preheating temperature 1300 F. A neutral flame is generally employed, although a slightly carburizing flame is sometimes advantageous, as, for example, when there is a deficiency in carbon.

In making a weld the crack is chipped out to form a 75 to 90 deg V, a little flux is spread over the starting point, and the flame is played on the V until the walls begin to melt. The metal of the outer walls of the V should not melt ahead of the metal at the root. The rod, dipped in flux, is then brought to a red heat and rubbed into the molten metal. The tip of the blue cone of the flame should be kept $\frac{3}{16}$ to $\frac{1}{8}$ in. away from the molten puddle to avoid hard spots and loss of silicon and carbon.

Cast-iron rods are used for gas welding. The A.W.S. recommends C, 3.0 to 3.5; Si, 3 to 3.5; Mn, 0.5 to 0.75; S, 0.1; P, 0.5 to 0.7.

Metal-arc Welding. Cast iron may be welded with ferrous electrodes in two ways: (1) hot, with preheating; (2) cold, without preheating. The purpose of preheating is

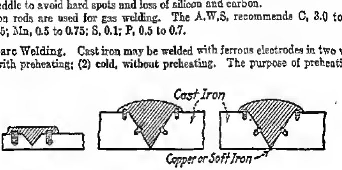

FIG. 8.—Cross Sections of Studded Joints, Showing Use on Thin and Thick Materials and the Use of a Copper or Soft Iron Strip at Bottom of Vee.

the same as in gas welding. The preheating temperature is usually 1000 to 1300 F. Cast-iron electrodes are used for hot welding. The composition is practically the same as for gas welding. Currents range from 300 to 1,500 amp, 400 to 600 amp being common. The voltage is 40 to 70.

The cold welding process is used for welds that need not be machined and that are not thick.

Mild steel-covered electrodes are generally used. The coating of the electrode may shield the arc and weld metal, or it may alloy with the steel core to produce a cast-iron deposit. The coating for the first purpose is the same as on ordinary mild steel-covered electrodes and is designed to avoid nitrides. Carbonaceous coatings are used for the second purpose. A coating of 40 to 60 percent graphite, 1 percent barium carbonate, and the rest carborundum, with a paste of water glass as a binder, has been found to be effective.

The amperage used for covered electrodes in cold welding is kept low in order to reduce heat, hardening, and cracking. The use of 80 to 90 amp with a $\frac{1}{8}$ in. electrode on $\frac{1}{2}$ in. material is common.

Much of the success of cold welding depends on proper preparation of the joint. Studding is a common method (Fig. 8). The size of studs and spacing depends on the thickness of the casting. Copper, lead, or soft-steel inserts are used to ensure machinability on one side.

Carbon-arc Welding. Preheating from 750 to 1300 F is used together with annealing or slow cooling. Graphite rods are generally used, and a flux containing equal parts sodium carbonate and sodium bicarbonate is useful. Filler rods are generally the same as for gas welding.

Thermit Welding. (See p. 1842.)

Bronze Welding. Preheating is usually applied to assure success and may be local or general depending on the casting. A black preheat is generally employed, although in some cases preheating to 1650 F has been found advantageous.

The large volumes required for Carrene 1, F-11, dieline, and water vapor can be handled satisfactorily by centrifugal compressors. When the evaporating pressure is below atmospheric, as in the case of Carrene, dieline, ethyl chloride, sulfur dioxide, water vapor, and butane, air leaks are likely to be excessive; where the refrigerant is nearly odorless (Freon 12 and methyl chloride) leaks into the atmosphere and loss of the refrigerant may be excessive.

Water vapor can be used only for very mild refrigeration. With a centrifugal vapor compressor of 5 or 6 stages the variation in capacity with the temperature of the chilled water is about as follows:

Temp of chilled water, F	60	55	50	45	40	35
Percent rating, tons	142	119	100	84	69	58

Ammonia is used extensively in the United States for commercial work; in 1938 the Freon refrigerants had been adopted by only 15 percent of the new compressors of 26 to 100 tons capacity and only 2 percent of those over 100 tons. Ammonia is dangerous to life and corrodes copper and copper compositions. It has a high latent heat of vaporization, its pressures and

84. $\int \sinh x\,dx = \cosh x + C$

85. $\int \tanh x\,dx = \log_e \cosh x + C$

---

* If p or q is an odd number, substitute $\cos x = z$ or $\sin x = z$.

specific volumes are convenient, and it is not miscible to any large extent in the usual mineral oils. Leaks are easily detected by the use of sulphur dioxide vapor. **Carbon dioxide** has been used as a safety refrigerant for a long time; its presence in large volume in a confined space is not a serious hazard unless the exposure is prolonged. Its condensing pressure is very high for condenser water initially at 70 F and higher. Its critical temperature is 87.8 F and consequently with cooling water of about 80 F it will not condense; the power consumption is high (see Table 2). **Sulphur dioxide** is used almost entirely in fractional tonnage machines in which it lends itself to the air-cooled condenser. It is not inflammable, but is an irritant and a toxic gas. It is practically harmless in the small household refrigerating machine but may be dangerous in multiple systems.

Unless sulphur dioxide is anhydrous, it will corrode the common metals used in the construction of pressure vessels. **Methyl chloride** (CH_3Cl), an anesthetic in amounts of 5 to 10 percent by volume, may be used in air-cooled condensers and is successful in large and small-sized units. It is miscible in mineral oils; water in the system will freeze in the expansion valve. Leaks may be detected by the use of acrolein. **Dichlorodifluoromethane** (F-12) is not toxic, inflammable, or irritant. An air-cooled condenser may be used, and leaks can be detected with a special torch. **Ethyl chloride** (C_2H_5Cl), **butane** (C_4H_{10}), and **propane** (C_3H_8) have as yet been used but little as refrigerants. The use of **dieline** ($C_2H_2Cl_2$) and **Carrene** (CH_2Cl_2) has been confined to the centrifugal compressors. Very low temperature refrigeration may use ethane, ammonia, or Freon 12. Other halides such as F-11 (CCl_3F), F-21 ($CHCl_2F$), and F-114 ($C_2Cl_2F_4$) are also available.

The refrigerant used for air-conditioning and commercial cooling is largely F-12 or methyl chloride; the similarity of physical properties permits the use

by a weak solution of ammonia in water. (6) The pump, which returns the rich liquor from the absorber to the generator. The Electrolux-Servel process (p. 1873) permits the omission of the pump or other moving part.

Between the generator and absorber, there are two channels of communication: one through the condenser, expansion valve, brine coil, absorber, and pump, as noted above; through the other, the weak solution in the generator passes directly to the absorber and there absorbs the gas coming from the brine coil. As in the compression system, there is a region of high pressure including the generator and condenser, and a region of low pressure including the brine coil and absorber. The pump is used to force the strong solution from the lower pressure of the absorber against the higher pressure in the generator.

For efficient operation of an absorption system, certain auxiliary organs are required. The **analyzer** forms the upper part of the generator and receives the rich solution from the pump. The solution descends over a series of disks or trays until it meets the boiling liquid in the still. The vapor rising from the still thus comes into intimate contact with the descending liquid and is enriched in ammonia and deprived of water.

The **rectifier** is placed between the generator and condenser. It consists of a coil surrounded by cooling water, and its function is to remove water vapor from the mixture of water and ammonia vapors driven off from the generator.

The **exchanger** is placed between the generator and absorber. In it, the hot weak solution passing from the generator to the absorber gives up heat to the cooler strong solution passing from the pump to the generator.

Ammonia Solutions. The analysis of an absorption system requires a knowledge of the properties of ammonia solutions. Certain of these properties have been investigated by Wilson (*Univ. Illinois, Eng. Expt. Stat. Bull.* 146).

The **concentration** of a solution of ammonia in water is defined as follows. Let y denote weight of water, Z the weight of ammonia in the solution: then the **weight concentration** is $x' = Z/(Z + y)$ and the **mol concentration** is $x = (Z/17)/[(y/18) + (Z/17)] = Z(0.944y + Z)$. (For definition of the "mol" see p. 301.)

The relation between pressure, temperature, and mol concentration, as determined by Wilson, is given by the equation

$$T/T' = 1 + 0.70358(1 - x^k)$$

with

$$k = \sqrt{x + 0.05}(1.347 - 2.9x + 1.77x^2)$$

In this equation, T denotes the temperature of the solution, T' the temperature of saturated ammonia corresponding to the pressure on the solution, and x the mol concentration.

Table 16 gives the pressure on the solution for various temperatures and various values of x, the mol concentration.

The vapor in contact with the solution will be a mixture of water vapor and ammonia vapor, each with its own partial pressure. Table 17 gives the partial pressure of the water vapor as determined by Wilson for various temperatures and mol concentrations of the liquid phase. The partial pressure of the ammonia vapor is obtained by subtraction. Thus for $t = 120$ deg and a mol concentration $x = 0.35$, Table 16 gives for the total pressure 45.62 lb per sq in., and for the pressure of the water vapor Table 17 gives 1.06 lb per

of either refrigerant in the same unit machine. Ammonia is still the favored refrigerant in the larger installations, or in the central-plant-type, with brine systems, and with direct-expansion systems, such as ice plants and where the ammonia is restricted to the operating plants. Sulphur dioxide is now used but little.

Basis of Rating of Refrigerating Machines. The commercial unit of capacity of a refrigerating machine is taken as the abstraction of an amount of heat equal to the heat of fusion of 1 ton (2,000 lb) of ice per day (24 hr). The determinations of the heat of fusion of ice by the Bureau of Standards show slight deviations between plate ice, can ice, and natural ice. The mean of 21 determinations is 79.63 cal per g, or 143.33 Btu per lb avoirdupois. This is equivalent to 286,600 Btu per ton, or the taking up of heat in a machine of unit capacity at the rate of 199.028 Btu per min. This is so close to the convenient round figures of 200 Btu per min, 12,000 Btu per hr, or 288,000 Btu per day, that these latter figures have been adopted as the **standard ton** by the A.S.R.E. and the A.S.M.E.

The rating of the tonnage of a refrigerating machine taken in connection with the plane of temperatures at which heat is to be taken up and that at which it is to be discharged (*i.e.*, temperature of the refrigerant in the evaporating or refrigerator coils and the highest temperature in the condenser) has not been fully agreed upon internationally. European engineers use +14 F at the refrigerating coil and +77 F at the condenser, but in America the **standard rating** is the number of standard tons of refrigeration under pressures which correspond to a saturation temperature of 5 F (−15 C) for the inlet pressure and 86 F (30 C) for the outlet pressure, these pressures being measured outside and within 10 ft of the refrigerating machine, measured along the inlet and outlet pipes, respectively. This is equivalent in ammonia machines to 34 lb abs and 169 lb abs, respectively. For the influence of change in the plane of temperatures on the ideal performance of refrigerating machines see Tables 2 and 3.

The refrigerating capacity of a machine is different from the actual **ice-making capacity** of a plant; the latter is considerably less, being 50 percent and upward of the refrigerating capacity, according to temperature of water, etc.

The Refrigeration Research Committee of the (British) Institution of Mechanical Engineers has adopted (1914) the calorie per second (= 342,860 Btu per 24 hr) as the unit of refrigeration, and has adopted as "standard conditions" a temperature range of the cooling water from 15 C (59 F) at inlet to 20 C (68 F) at outlet and a temperature range of the brine from 0 C (32 F) to −5 C (23 F). For direct-expansion systems, the standard vapor temperature in the refrigerator is to be taken as −10 C (14 F). The rated capacity of a machine is the number of units of refrigeration developed under the foregoing standard conditions.

Compression System

The influence of the head (or liquefaction) temperature on the theoretical coefficient of performance of a compression machine is as follows for **various refrigerants** with a common suction (or evaporation) temperature of 5 F.

The influence of increased head temperature is seen to be especially great for **carbon dioxide**; a consequence of its proximity to the critical temperature. Special procedures such as two-stage compression are necessary for carbon dioxide when cooling-water temperatures are high—as in the tropics. For example, with 300 lb suction pressure (temperature 0 F approx.) and with the compressed gases cooled to 95 F, the theoretical coefficients of

sq in.; hence the partial pressure of the ammonia vapor is 45.62 − 1.06 = 44.56 lb per sq in.

The tables of total and partial vapor pressures are required in analyzing conditions in the rectifier. The following example illustrates the process.

Let the pressure in the generator be 150 lb per sq in. and the average mol concentration $x = 0.30$. From Table 16, the solution will have this pressure when the solution attains the temperature 217 F approx. and from Table 17 the partial pressure of the water vapor above the solution is 11.1 lb per sq in. In the rectifier, let the mixture of vapors be cooled to 140 F. With a total pressure of 150 lb, the mol concentration of the condensed liquid must be 0.50, and from Table 17 for $t = 140$ deg and $x = 0.50$ the partial pressure

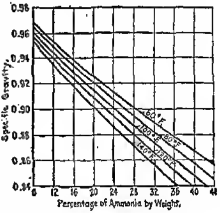

FIG. 1.—Relations between Temperature, Specific Gravity, and Weight Concentration of Aqua Ammonia.

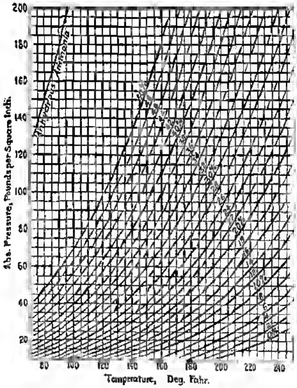

FIG. 2.—Relations between Temperature, Pressure, and Weight Concentration of Aqua Ammonia.

of the water vapor is 1.37 lb. The reduction in partial pressure from 11.1 to 1.37 lb means that only about ⅛ of the water vapor initially in the mixture

performance are as follows: discharge pressure 1,200 lb per sq in., 1.70; discharge pressure 1,400 lb, 2.095; in two stages (1) to 1,200 lb with cooling to 95 F and (2) to 1,400 lb, 2.25.

Table 8. Influence of Head Temperature on Coefficient of Performance
(Suction temperature 5 F)

Refrigerant		Ammonia	Carbon dioxide	Sulphur dioxide	Freon 12
Coeff. of performance with head temperature of	70 F	6.16	4.17	6.29	6.15
	86 F	4.77	2.14	4.69	4.71

Volumetric Efficiency. The volumetric efficiency of a compression machine is the ratio of the actual weight of vapor pumped by the machine to the weight calculated from the displacement of the compressor with gas entering saturated at its evaporating pressure. This efficiency, on account of heating of the gas coming to the cylinder and in the cylinder, of reexpansion from clearances, and of slip, varies from 60 to 85 percent. Compression machine builders under favorable conditions will guarantee a volumetric efficiency of 80 to 85 percent in machines of 50 tons and over; under good average working conditions, with a reasonable amount of care to maintain tight valves and tight piston rings, it should run from 75 to 80 percent.

Theoretical values of compressor displacement for ammonia are given in Table 9.

51	35	1.70	1.72	1.74	1.76	1.77	1.79	1.81	1.83	1.85

Example. Let head pressure = 198.9 lb per sq in. abs and back pressure = 30.42 lb per sq in. abs. Then h_{g1} = 611.8 Btu and h_f = 150.5 Btu. Also, V'' = 9.116 cu ft per lb. The weight of ammonia per min = 200/(611.8 − 150.5) = 0.434 lb, and cfm = 0.434 × 9.116 = 3.96. Assuming the volumetric efficiency of compressor = 80 percent, the actual piston displacement = 3.96/0.80 = 4.95 cu ft per ton of daily capacity.

The theoretical horsepower required to produce 1 ton of refrigeration under different operating conditions with ammonia is given in Table 10. The

is carried on to the condenser. The remainder is condensed and returned (as a strong aqueous solution) to the generator.

Condenser Pressure and Back Pressure. The lower the pressure and temperature in the condenser coil, and the higher the pressure and temperature in the evaporator (back pressure), the more economical will be the working of the plant. For these reasons, the cooling water in the condenser should be used as cold and in as large quantity as possible, and the back pressure should be as high as possible. In ammonia plants in which the temperature is to be kept at about 32 F, by direct expansion, a back pressure of about 33 lb gage (corresponding to about 20 F) is generally maintained. If brine circulation is used, the brine enters the room with a temperature of about 20 F and returns with a temperature of 24 to 26 F; the back pressure in the ammonia coils should be 25 to 28 lb gage, corresponding to a temperature of 10 to 15 F.

During the chilling stage in a packing house, the temperature in the room may rise in the beginning to 50 F and a higher back pressure—about 60 lb gage, corresponding to a temperature of about 40 F in the ammonia coil—is maintained. As the temperature falls in the room, the back pressure is decreased to the point corresponding to the desired temperature of the room, usually about 30 lb gage. If temperatures of 0 F and below are required, the back pressure should be 4 lb gage, corresponding to a temperature of −20 F. For ice making, the back pressure in ammonia coils is 20 to 28 lb gage, corresponding to a temperature of 5 to 15 F.

Wet Compression vs. Dry Compression. The considerable superheat of ammonia vapor at the end of compression may be reduced or prevented by carrying liquid ammonia into the compressor. If sufficient liquid is admitted to keep the vapor always in a saturated condition, the operation is known as **wet compression.** If the ammonia gas is dry or superheated when admitted to the compressor and there is no liquid injected during the compression stroke, the operation is known as **dry compression.** Wet compression is now practically obsolete.

The **multiple-effect system** may be used in plants where there are both high- and low-temperature systems. In this, the higher-temperature gases are admitted to the cylinder at or near the end of the suction stroke and raise the ultimate suction pressure to that of the high-temperature system,

developed depends on the mean concentration $x = \frac{1}{2}(x_1 + x_2)$. According to the experiments of Hilde Mollier, the heat of solution q_s per lb of ammonia is given by the equation $q_s = 345(1 - x) - 400x^2$. For $x = 0.59$, q_s reduces to zero and for all higher values of x, the heat of solution is zero. See Table 18.

[a] Average concentration; percent of ammonia by weight.

The **heat that must be taken from the absorber** is made up of three parts: (1) the heat that must be abstracted from the entering vapor to convert it into liquid at the temperature of the absorber; (2) the heat of solution q_s; (3) the heat that must be absorbed in reducing the temperature of the weak solution to that of the strong solution leaving the absorber. The first of these is the difference of total heat of the ammonia in the initial and final states; the second is given by the preceding formula; the third is the product of the weight of weak solution per pound of ammonia, the specific heat, and the temperature difference. The specific heat averages about 1.05. The **heat of absorption** Q_a is the sum of (1) and (2). Values of this quantity are given in Table 19.

For example, let the concentrations be 0.25 and 0.35, whence per pound of ammonia circulated, 6.5 lb of weak solution enters the absorber at, say, 100 deg, and 7.5 lb of strong solution leaves the absorber at, say, 80 deg F. The pressure in the absorber is 20 lb abs., and ammonia gas enters at a temperature of 5 deg. Under these conditions the three quantities of heat are as follows: (1) To condense the gas, $h_1 - h_3 = 486.2$ Btu; (2) heat of solution $q_s = 345(1 - 0.30) - 400 \times 0.30^2 = 205.5$ Btu; (3) to reduce temperature of 6.5 lb of weak solution from 100 to 80 deg, taking the specific heat as 1.05, $6.5 \times 1.05 \times (100 - 80) = 136.5$ Btu. Total heat removed from the absorber $486.2 + 205.5 + 136.5 = 828.2$ Btu.

In the **generator** the **processes** are the reverse of those in the absorber. Heat is supplied from an external source and is used for the following purposes: (1) to separate the liquid ammonia from the solution; (2) to vaporize the liquid and superheat the vapor; (3) to raise the temperature of the solution. In practice, additional heat must be supplied to vaporize some of the water. The calculation follows the method indicated for the absorber.

Heat Balance. For 1 lb of ammonia passing through the expansion valve, the following quantities of heat are absorbed or rejected at various points of the system:

Q_1 = heat imparted to the fluid in the generator.

Q_2 = heat absorbed by fluid in the brine cooler.

thereby increasing the capacity of the machine to that corresponding to the high temperature gas. This system is of value only where the condensing water is of high temperature (say about 90 F) and, with ammonia, where there are in service refrigeration systems at two widely different temperature levels (say 20 to 30 deg apart), and further where these systems are so relatively proportioned that they can be handled in one machine. Any increase in load at one temperature reduces the capacity of the compressor for the other. The existing installations are most used for ice making with high-temperature condensing water. Carbon dioxide machines for use in tropical countries have also been built on this principle for the purpose of improving the capacity and efficiency of the machine. Part of the carbon dioxide coming from the condenser is throttled to about 450 lb per sq in. and is used for cooling the rest of the carbon dioxide which is then expanded down to some lower pressure, say 250 lb per sq in. The vapors at both pressures are compressed in a multiple-effect compressor. Under tropical conditions, an increase of 130 percent in refrigeration with an increase of 54 percent in required hp has been obtained (*Engineering*, Aug. 23, 1918, p. 201).

With a low-temperature system, and also for ice making, the compression may be carried out in two stages with intercooling either (1) by **compound compression** or (2) by the use of a **booster.** The compression ratio must be at least 5 or 6 to justify two-stage compression, except where there are two different refrigerating temperatures. In that case, the low-pressure cylinder compresses the low-temperature vapor only and the high-pressure cylinder admits both the high-temperature vapor and the discharge from the low-pressure cylinder. A compound compressor has both cylinders on the same shaft and operating at the same rpm. A *booster* is a comparatively cheap compressor, usually reciprocating, of relatively high rpm, and compresses the low-pressure vapor through a range of 25 to 50 lb per sq. in. The speed may be variable, and consequently the pressure of the booster discharge can be varied as the load and operating conditions vary. A booster increases the capacity of the high-pressure cylinder in direct ratio to the density of the high-pressure suction. A gain up to a maximum of 20 percent in efficiency over single-stage machines has been realised.

Tests by Horne (*A.S.R.E.*, 1922) on compound compression with a suction pressure of 13.8 to 14.8 lb per sq in. abs have yielded the following results:

Test Results on Compound Compression

Ratio of discharge to suction pressure (abs)....	8	10	12	14	16
Theoretical compression, ihp per ton with simple compression..........................	1.26	1.47	1.65	1.79	1.95
Theoretical compression, ihp per ton with compound compression......................	1.10	1.28	1.40	1.48	1.55
Actual compression, ihp per ton with compound compression........................	1.20	1.40	1.54	1.63	1.72

Intercooling was carried out between stages and approximately equal amounts of work were done in the two cylinders.

For temperatures below -25 F, a split system is sometimes used in which the condenser of a carbon dioxide system is cooled by brine or direct expansion from a standard ammonia system.

The compression system is most commonly used in the production of refrigeration. Electric current at low rates favors the motor-driven compressor so that a major proportion of installations are of this type. Diesel-driven compressors are available and are used in some localities, particularly

Q_3 = heat rejected by fluid in the condenser.
Q_4 = heat withdrawn from fluid in absorber.
Q_5 = heat equivalent of work of pump
Q_6 = heat loss by radiation, etc.

The following equation expresses the **heat balance** for the system:

$$Q_1 + Q_2 + Q_5 = Q_3 + Q_4 + Q_6$$

The heat Q_2 absorbed in the brine coils, as in the compression system, is $Q_2 = h_{g1} - h_{f2}$, where h_{g1} is the total heat of the saturated vapor corre-

Table 19. Ammonia Absorption Machine—Heat Removed in Absorber

The tabulated quantities are Btu per pound of ammonia absorbed. The pressure in the absorber is that corresponding to the temperature and pressure of the strong solution. The ammonia gas is assumed to be dry and saturated as it enters the absorber.

sponding to the temperature of the fluid in the brine coil, and h_{f2} is the total heat of the liquid corresponding to the temperature of the liquid entering the expansion valve.

If it is assumed that the **fluid** enters the condenser in the dry saturated state, the heat Q_3 is simply the latent heat r corresponding to the temperature of the fluid in the condenser.

The weight G of strong solution (concentration x_1) circulated per lb of ammonia liberated is given by the equation

$$G = (1 - x_2)/(x_1 - x_2)$$

where x_2 is the weak liquor concentration.

in the Southwestern portions of the United States, but are not generally considered where central-station current is available at reasonable rates. The compression machine has displaced the absorption machine (except in isolated cases and more especially on low-temperature refrigeration) in consequence of its higher efficiency and better control of the operating cycle. The development of two-stage high-speed intercooled compressors has increased the advantage of the compression over the absorption machines.

Unit machines have been standardized and are available in capacities from 100 lb to 100 tons. The unit machine includes motor-driven compressor, condenser, controls, gages, and valves, arranged in a compact assembly at the factory, available from stock, ready for installation by connecting to the coils or devices to be cooled.

Electric Drives. Where **direct current** is available, capacity and temperature control is readily obtained by varying the speed of the motor, either manually or automatically, by means of a variable resistance in the shunt field. With **alternating current**, capacity and temperature control is obtained (1) by *intermittent operation*; (2) by *adjustable clearance pockets* in the compressor cylinder or heads; (3) by the use of an unloading device by means of which the compressor valves are held off their seats; and (4) by the use of motors wound for two or more speeds. The common practice is to use motors of repulsion induction-start type for the small machines, slip ring or wound secondary type for intermediate capacities, and self-starting synchronous motors for intermediate and large capacities. A **flywheel type motor** mounted directly on the compressor frame gives the necessary flywheel effect in the rotor.

Horsepower of Engine Driving Compressor. The indicated horsepower of the engine available should be about 20 percent greater than the indicated compressor horsepower for compressors up to 20 tons capacity, 15 percent greater from 20 to 100 tons, and 10 percent from 100 tons to 500 tons. For motor-driven compressors, the motor should have at least 25 percent greater power than the indicated compressor horsepower, and on small machines of 10 tons and under from 35 to 50 percent greater to supply sufficient starting torque, especially in automatic machines. This allowance should be made upon the horsepower of the gas compression based upon the highest probable condenser and suction pressure under which it may be necessary to operate.

The enclosed type of compressor, of the single-acting vertical design with 2, 3, or 4 cylinders, is commonly used, but the V type is also available with 4, 6, 8, and up to 16 cylinders. Piston diameters range from 1½ to 12 in. The stroke is short, frequently two-thirds the piston diameter. Valves are usually of the ring-plate type, made of chrome-vanadium steel, hardened and ground to a true surface; the lightweight spring-balanced cushioned poppet valve is still used. Lubrication is forced, and the oil pump is equipped with filters. Methyl chloride and Freon 12 as well as dieline are miscible in the usual lubricating oils, necessitating the use of a special oil trap. The pistons are supplied with oil rings as well as the usual compression rings.

The halide group of refrigerants (especially F-12) as well as methyl chloride operate well with air-cooled compressors with fins on the cylinders and permit a lighter construction. The water jackets on the compressor of a dry-compression ammonia machine change the compression curves only slightly. In single-acting machines, the compression line will usually fall slightly under the adiabatic, making a card about 4 percent smaller than the adiabatic. The control of the superheat is not attempted, the jacket water being used mainly to keep down the temperature of the lubricating oil and to increase the life of the gaskets. Jackets are sometimes

The pump forces G lb of rich liquor from the pressure p_1 in the absorber to the pressure p_2 in the generator. Hence if v is the volume of 1 lb of the rich liquor, $Q_5 = Gv(p_2 - p_1)/778$.

The heat Q_1 and the heat Q_4 may be calculated approximately by the method already indicated.

Tests by B. H. Jennings (*Refrig. Eng.*, Aug., 1935) of an absorption machine with 180 lb gage condenser and 25 lb gage absorber pressures show 35 lb of steam at 10 lb gage pressure used per ton of refrigeration per hour. The water requirements were 9.45 gpm per ton of refrigeration with 10 F rise of water temperature and 4.73 gpm with 20 F rise of temperature.

In the **intermittent absorption machine,** heat is applied to strong aqua in the generator and ammonia vapor is driven off and condensed. The liquid ammonia is stored in a receiver or evaporator until an automatic valve shuts off the heat. The generator is then cooled by water or air and then acts as an absorber for the vapor evaporated in the cooling coils. The temperature of evaporation will vary with the pressure existing in the absorber. There is no pump for the aqua, and one vessel is alternately absorber and generator.

Recent developments in Europe have produced two-stage absorption machines for very low temperatures with high efficiency. Another development is the resorption machine for moderate refrigeration with high efficiency.

In the **two-stage system,** the low stage absorbs suction gas from the evaporator at a temperature that may be as low as about −95 F (saturation pressure 1.52 lb per sq in. abs). The low-stage generator liberates the ammonia at about atmospheric pressure (−28 F). This vapor is now absorbed in the high-stage absorber from which point the procedure is that usual in the normal absorption process.

In the **resorption process,** the vapor from the generator is reabsorbed in weak liquor circulated from the evaporator and meeting this vapor in the resorber. From the resorber, the strong liquor goes to the evaporator which, as usual, sends its ammonia vapor to the absorber and returns its weak liquor to the resorber. This arrangement is suitable only for relatively high-temperature refrigeration but is claimed to be more efficient than the conventional system.

For further details and a list of references see A.S.R.E. Refrigerating *Data Book, 1939–1940, p. 47.*

There is no positive action of the absorption machine, and the capacity and efficiency depend to a large extent upon the skill and watchfulness of the operator. An absorption machine, under best conditions of design and operation, using low gas pressure, with a temperature in the refrigerator of not more than 0 F, and a capacity of 50 to 100 tons, gives refrigerating results practically equal to those of a steam-driven compression machine. For capacities exceeding 100 tons the compression machine is not only more positive but becomes more efficient. The absorption machine gives best comparative results as the suction pressures are reduced, the compression machine as they are raised. Absorption machines have been confined to comparatively small units (up to about 225 tons), while compression machines are now in successful operation with capacities as high as 1,000 tons.

Electrolux Servel Absorption Process. (Platen-Munters Patent.) The Electrolux Servel process is an ammonia-absorption process which eliminates the use of pumps or other moving parts. The gas pressure is uniform throughout the whole system and the difference in vapor pressure of ammonia in the condenser and in the evaporator is compensated by the

omitted on compound compressors with intercooling. The heat abstracted by the jacket water is seldom more than 2 or 3 percent of the indicated work.

Little attention is paid to keeping cylinder clearance low; it functions as a compressed spring and has little effect other than to reduce the pumping capacity.

Valves. The velocity through the suction valves should not exceed 4,000 fpm and through the discharge valves 10,000 fpm. With plate or feather valves, suction-valve velocities are kept under 2,500 and discharge valve under 6,000 fpm.

Connections. Suction and discharge connections to the cylinder are usually based on a velocity of not over 4,000 fpm, although the discharge pipe line to the condenser may be based on a velocity of 8,000 to 10,000 fpm, depending upon the length of line, fittings, etc. With receivers located close to the compressor inlet, the suction pipe velocities may be increased considerably.

Centrifugal Compressors. For refrigerants having liquefaction pressures of one atmosphere or less, the centrifugal compressor, with its capacity for handling large volumes, is preferable to the reciprocating compressor. In multistage compressors, there is also the advantage of interstage cooling. This type of compressor has been applied to water vapor, Carrene, dieline, Freon 12, and F-11.

Performance of Ammonia Compression Machines. Table 11 shows the effect on capacity and horsepower of varying the condenser and refrigerator temperatures.

Table 11. Variation in Capacity and Horsepower Required in Ammonia Compression Machines with Variation in Operating Conditions

(The values in this table are the ratios of the capacity and horsepower under the stated operating conditions as compared with capacity and horsepower when operating between 0 and 95.5 F.—York Mfg. Co.)

Household refrigerating machines are designed for continuous automatic operation and for conservation of the charges of refrigerant and oil. These units are almost universally motor-driven compressors, the principal exception being the Electrolux-Servel absorption unit (see p. 1873). The compressor may be hermetically sealed, with the compressor and motor enclosed in the same casing, or may use a shaft seal, embodying some form of sylphon bellows, with an outside coil spring at the place where the crankshaft passes out of the casing. The compressor is generally reciprocating, but rotary types are being increasingly used either with a floating piston ring driven by an eccentric or with sliding blades. Lubrication is by internal forced-feed circulation in most cases. The condenser may be of the radiator, coil, or plate type, cooled by natural draft, by a fan on the main motor, or by a separate motor. The refrigerant is most commonly sulphur dioxide or Freon 12. Refrigerant feed control to the evaporator may be (1) float feed

presence of hydrogen in such quantity that the sum of the partial pressures of the hydrogen and of the ammonia vapor in the evaporator is equal to the ammonia pressure in the condenser. The general arrangement is shown in Fig. 3. Strong ammonia liquor (ammonia dissolved in water) in the lower portion, *L*, of the generator, *G*, is heated by a gas flame and the resulting slugs of ammonia vapor and ammonia liquor rise in the external tube *I* and discharge in the upper portion of the generator and are separated there. The ammonia vapor, carrying with it a small amount of water vapor, passes through the pipe *P*, to the rectifier *R*, where much of the water vapor is condensed and returns through *P* as a strong liquor to the generator. The ammonia vapor passes to the condenser *C* and returns as a liquid to the lower portion of the rectifier chamber. It then flows through the gas heat-exchanger *D*, where it is cooled, to the evaporator *E*. In the evaporator it meets

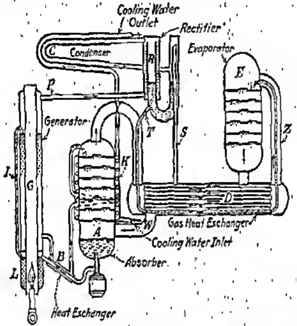

Fig. 3.—Electrolux Servel Absorption Process.

hydrogen and evaporates at a comparatively low partial pressure, and consequently at a low temperature. The evaporated ammonia, together with the hydrogen into which it has diffused, pass through the gas heat exchanger *D* and through the pipe *W* to the absorber *A*. In the absorber it meets weak liquor coming from the lower portion of the upper chamber of the generator, the weak liquor having been cooled on its way to the absorber by passing through the liquid heat-exchanger *B*. The resulting strong liquor formed in the absorber passes through the liquid heat-exchanger to the lower chamber of the generator. The hydrogen, which accompanied the low temperature ammonia vapor to the absorber, passes out by the pipe *Y* from the upper portion of the absorber and returns to the evaporator through the gas heat-exchanger *D*, being cooled (in passage) by the cold vapors passing from the evaporator to the absorber. A pipe *S* permits the return to the evaporator of any hydrogen which may have been carried in solution by the strong liquor in the absorber and liberated in the generator.

Tests made at the National Physical Laboratory (England) have shown, for a small unit, a ratio of refrigerating effect to heat supply of about 38 percent with 45 F cooling water and about 30 percent with 63 F cooling water.

(flooded system), (2) pressure-actuated diaphragm valve, or (3) by fixed orifice. The fixed orifice may be either a plate orifice or a capillary tube. Rotative speeds of the compressor vary from 300 to 600 rpm. The compressor is air-cooled except for the hermetically sealed unit (which is air-cooled indirectly) and has fins on the cylinder casing. The evaporator is usually made of stainless steel, tin-plated brass, or tin-plated copper. Controls are generally pressure-operated thermostatic switches. The power consumption of an average box (say 6 cu ft) is about 20 kw-hr per month. The heat gain of a refrigerator cabinet of the same size is about 3.3 Btu per hr per deg F.

Table 12. Test Results on Ammonia Machines at Quincy Market Cold Storage and Warehouse Co.[a]

1 and 2, cross-compound Corliss engines; 3, two-stage feather-valve compressor driven by uniflow engine; 4, two-stage electrically driven compressor; 5 and 6, tandem compound engines; 7, absorption machine.

[a] The discharge pressures in these tests are exceptionally favorable and result in low power consumptions.

The absorption machine in the preceding table was more economical than the 400 ton compression machine with the low-temperature suction gas and less economical than the same machine with high-temperature suction gas.

Station operation results show that absorption machines require 25 to 35 lb of steam per ton of refrigeration with 0 deg brine and 150 lb condenser pressure. Makers guarantee [illegible] to [illegible] lb of live steam per hour per ton of ice.

Condensers

(For heat transfer rates, see *Eng. Exp. Sta., Univ. Illinois*, Bull. 171, 186)

For unit types (F-12 and methyl chloride), pipe coil condensers are generally used. In central plant installations, particularly with ammonia, shell and tube condensers are most common.

Air-cooled condensers are common with low-pressure refrigerants, with and without fan circulation, for units up to 50 tons. Water-cooled condensers are used on larger plants and with ammonia or carbon dioxide.

The atmospheric condenser, in use on some ammonia machines, is usually a vertical return-bend coil of 2 in. pipe, 20 ft long over-all, usually 12 pipes high. Water flows downward over the pipes through a distributing device on top of each coil; gas usually enters at the bottom, flows upward through two or more lengths to remove superheat, then passes to the top and flows downward to the remainder of the coils. With 70 F condenser water maintaining 155 to 160 lb condenser pressure, a common rating is 1 ton of refrigeration for each 20 ft pipe, including return bend.

Advantages and Disadvantages of Absorption System. The absorption system would be favorably indicated where exhaust steam is available at about atmospheric pressure. The repair costs may be heavy when over driven and when using a corrosive water in the absorber and rectifier. Slight quantities of oil have a very bad effect upon its efficiency. Faulty rectification, due either to faulty design or operation, is one of the greatest sources of loss; this defect may reduce seriously the capacity of the machine. The best systems of rectification consist of an efficient analyzer, a mechanical separator, a cooling coil, and preferably a second separator with liquid drip after the cooling coil for the purpose of testing the results of rectification. At the full capacity of the machine, 1 to 5 percent of the water vapor is usually carried through the rectifier to the condenser and cooler. The analyzer, first separator, and cooling coils discharge their drips as returns to the generator; the drip from the final separator gives an indication of the condition of the rectified gas, which should be used as a basis for the regulation of the machine. Careful operation will make purging of the cooler necessary only once in three or four weeks.

Surfaces Required. The surface area of the generator coils varies with the steam pressure, approximate values for 60 deg F condensing water and 0 deg brine being 14 sq ft per ton for 5 lb (gage) steam pressure, 10 sq ft for 20 lb, and 6 sq ft for 50 lb. The rectifier surface varies from 1.5 to 4 sq ft per ton, the exchanger surface is about 6 sq ft per ton, the brine-cooler surface averages about 15 sq ft per ton.

Trouble is frequently found from the formation of permanent gases; this will occur when air is present in the system. The addition of 0.2 percent of sodium bichromate, based on the total weight of the aqua charge, eliminates this trouble (McKelvy and Isaacs, *Jour, A.S.R.E.*, Mar., 1918).

Adsorption. Certain inert solid materials, such as activated charcoal, the chlorides of calcium, barium, and strontium, ferric hydroxide, activated alumina, silica gel and other gels, have the ability to condense certain vapors by adsorption. An adsorbent for refrigeration purposes must be a good conductor of heat and be able to adsorb a large weight of the refrigerant per unit weight of the adsorbent material. Silica gel can be used with sulphur dioxide but not with ammonia; as it is a poor conductor of heat, the beds of the gel must not be thick. During adsorption, the liquefaction heat has to be removed; in commercial work, this is done by means of a water-cooled pipe surface.

In an adsorption process, the vapor adsorbed (SO_2, H_2O, etc.) passes from the vapor to the liquid phase directly without going into solution as in the absorption machine. This makes the adsorption machine simpler in design and operation.

Silica-gel Adsorption System of Refrigeration. Silica gel is a hard glassy material with the appearance of clear quartz sand. It is pure silicon dioxide and is chemically inert toward practically all substances and particularly all refrigerating mediums commonly used, with the exception of ammonia. It is made by treating sodium silicate with an acid to form a colloidal solution which sets as a gelatinous mass, and this, when washed, purified, and dried, becomes a silica sponge which is granulated to a size of 8 to 20 mesh. It has the property of adsorbing large quantities of vapors or liquids. While adsorbing, the heat of vaporization is liberated and must be carried away by air or other cooling agent if the temperature is to be kept down. The adsorbed substance is given up on activating the gel by heat.

The atmospheric drip condenser is of the same general construction as the atmospheric condenser, with the exception that each return bend has a trap drip connection through which the condensate is drained from each pipe. Commercial ratings in the drip type are usually approximately double that of the plain atmospheric type.

Combined with a cooling tower or water sprays, the atmospheric condenser becomes an evaporative condenser and is in general use for comfort cooling in cities where conservation of water supply is necessary.

Double-pipe condensers are usually constructed of 1¼ in. inner and 2 in. outer pipe, condensing water flowing through the inner pipe. In this type, ammonia gas enters at the top of the coil, liquid ammonia draining at the bottom; water enters at the bottom flowing countercurrent and out at the top.

Table 13. Heat Transmission through 2 × 3 in. Double-pipe Ammonia Condensers and Brine Coolers

200	1.34	1.165	165	1.54	1.55
250	1.64	1.180	155	1.46	1.94
300	1.88	1.240	148	1.40	2.33
400	2.40	1.300	140	1.33	3.11

Table 13 shows the rate of heat exchange with varying velocities of fluid for double-pipe (2 and 3 in.) ammonia condensers and brine coolers. Table 14 gives results of tests on a 1¼ × 2 in. double-pipe ammonia condenser, showing the effects of varying the amount and velocity of the condensing water at 70 F; gage suction pressure, 15.66 lb per sq in.

Shell and coil condensers have a cylindrical shell, usually of steel, inside of which are placed a number of helical coils with tails extending through stuffing boxes in either of the connecting headers. Ammonia gas enters the shell at the top; water enters at the bottom with countercurrent flow. The customary allowance is 12 to 16 sq ft of coil surface per ton, subject to the velocity and temperature of the water available.

Shell and tube condensers have a cylindrical steel shell filled with straight tubes expanded into tube sheets and are used both vertically and horizontally; size of tubes ranges from 1 to 2½ in., length of tubes up to 20 ft. Vertical condensers are generally open with the water flowing into an open water box on the top head, down through the tubes, and then through an open bottom head to a tank, or waste way. There is usually a device set into the tubes on the top head to distribute the water in a thin film on the surface of the tubes, sometimes with distributors to give it a spiral flow. Some vertical and all horizontal types have closed heads with water under pressure filling the tubes and with multiple passes; average velocities used

The internal volume of the gel is approximately 50 percent of its total volume, and in refrigerating practice, under normal conditions of operation, it will adsorb 25 to 35 percent of its own weight of SO_2.

Its use in commercial service (up to the present time) has been mainly freight-car refrigeration. The refrigerating system as applied to this service, consists of adsorbers, condenser, and evaporator with float valve feed to evaporator; the heat for activating the adsorbers is obtained from gas burners supplied from tanks of propane.

The silica gel is contained in ¾ in. steel tubes welded into headers. One adsorber carries 1,000 lb of silica gel, giving an ice-melting effect of 1 to 1½ lb per 24 hr per lb of silica gel, depending upon the evaporator and adsorber temperatures, with a possible 4 lb per pound of gel with forced circulation. The fuel consumption is approximately 135 lb of propane per ton of refrigeration.

The cycle of operation is as follows: the liquid refrigerant, coming from the condenser passes through an expansion valve, controlled by a float, into the

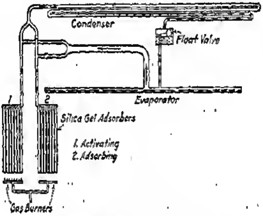

Fig. 4.—Silica-gel Refrigeration System.

evaporator (of the flooded type) and is there vaporized, absorbing heat from the chamber to be refrigerated. The vapor is then adsorbed in the pores of the silica gel. When the gel is approximately saturated, heat is applied to a battery of tubes carrying the gel and the refrigerant is driven out of the gel, as a vapor, to the condenser, where it is liquefied and returned to the evaporator. After the refrigerant content of the gel has been reduced to a certain limit, the heat is turned off and the gel is allowed to cool to a temperature at which it will again readsorb the vaporized refrigerant from the evaporator.

Multiple adsorbers will produce constant refrigeration, one or more acting as an adsorber while the other is being reactivated by evaporation to the condenser. The control of the fuel gas burners may be based upon a fixed timing or (by means of a thermostat) upon the temperature of the silica gel. The medium used is sulphur dioxide, but other fluids are possible. The control, as applied to refrigerator cars, is automatic, on a time basis, subject to the car thermostat, and consists mainly of control of the gas valve to the burners, with a thermostatic safety element.

The **Ice-O-Lator** of Prof. F. G. Keyes uses ammonia as the refrigerating fluid and employs, as a solid adsorbent, a calcium chloride sponge treated with other substances to increase its adsorbing power. Automatic control

are 3 to 6 fps. Commercial ratings vary from 8 to 15 sq ft effective surface per ton. This type of condenser has largely superseded other types in ammonia installations of sizes from 1 ton up.

For heat-transfer coefficients see Table 22.

Ammonia Piping and Fittings

Three general types of fittings are now furnished by a number of manufacturers: (1) the **gland end**, in which the fitting is tapped with the regular pipe thread, outside of which is a recess for a rubber washer, which is pressed into the recess and against the pipe at the joint by a gland which slips over the pipe (now practically obsolete); (2) the **flanged end**, which usually makes a tongue-and-groove joint with its companion flange; (3) the **threaded end fitting**, which may or may not have a recess at the outer end for soldering. The defects of the soldering method are (*a*) when used on lines larger than 3 in., the vibration, expansion, and contraction ultimately break the soldered joint, allowing the fitting to leak; (*b*) when used on the discharge gas line of a compressor operating at a pressure of 175 to 200 lb, the temperature of the gas, which often reaches 300 F or more, brings the solder to a plastic state where it is of little or no value for maintaining a tight joint. Welding is coming into extensive use, wherever practicable, for all piping and coils, eliminating fittings, reducing costs, and maintaining tightness.

Absorption System of Refrigeration

The essential organs of a vapor absorption system are:

(1) The **generator** or still, in which ammonia is driven off from a solution of ammonia in water by a steam coil. The generator takes the place of the compressor in the compression system. (2) The **condenser**, in which the ammonia gas is condensed. (3) The **expansion valve**. (4) The **brine coil**, in which the ammonia, by vaporizing, absorbs heat from the brine. (5) The **absorber**, in which the ammonia returning from the brine coil is absorbed

cuts off the heating gas supply after a definite amount of ammonia has been driven off from the adsorbent and liquefied, and turns on a water valve for cooling the generator. Distillation takes 45 min, adsorption 2 to 6 hr. The general method of operation is similar to that of the silica-gel process described above.

Methods of Applying Refrigeration

Refrigeration is carried out either by direct expansion or by the use of brine. The direct-expansion system of cooling is regular practice with Freon, methyl chloride, and carbon dioxide installations and with ice-making plants using ammonia. With the **flash method of direct expansion**, the liquid, at approximately the condenser pressure, is fed through an expansion valve directly into the piping which is to be used for cooling. The liquid spray from the expansion valve passes through the coils at high velocity, maintaining a wetted inner surface, and is vaporized by the absorption of heat through the pipe walls. With the **flooded method** (used especially in ice making), the coils are filled with liquid and communicate with a drum placed above them in which a constant liquid level is maintained. The vapor formed in the coils goes to the drum.

In the **brine system**, the direct-expansion system is used for cooling brine and the cooled brine is pumped through pipe lines to the point where the cooling is to be done, the heat being absorbed by the brine and the brine returned to be again cooled. The brine-cooling vessel is usually either a double or triple pipe coil or of the shell-and-tube type.

Brine Coolers

There are three types of coolers in general use, the submerged coil, double pipe, and shell and tube.

The **submerged coil** in a brine tank is used little except in ice manufacture. The **double-pipe cooler** is usually of 2 in. inner or brine flow pipe

Figure brine leaving cooler at least 5 deg higher than temperature of ammonia. Add 20 percent to above capacities if coolers are flooded. Add 10 percent to above capacities if coolers are submerged in brine.

86. $\int \cosh x\,dx = \sinh x + C$ 87. $\int \coth x\,dx = \log_e \sinh x + C$

88. $\int \operatorname{sech} x\,dx = 2\tan^{-1}(e^x) + C$ 89. $\int \operatorname{csch} x\,dx = \log_e \tanh (x/2) + C$

90. $\int \sinh^2 x\,dx = \frac{1}{2}\sinh x \cosh x - \frac{1}{2}x + C$

91. $\int \cosh^2 x\,dx = \frac{1}{2}\sinh x \cosh x + \frac{1}{2}x + C$

92. $\int \operatorname{sech}^2 x\,dx = \tanh x + C$ 93. $\int \operatorname{csch}^2 x\,dx = -\coth x + C$

DEFINITE INTEGRALS

The definite integral of $f(x)dx$ from $x = a$ to $x = b$, denoted by $\int_a^b f(x)dx$, is the limit (as n increases indefinitely) of a sum of n terms:

$$\int_a^b f(x)dx = \lim_{n=\infty} [f(x_1)\Delta x + f(x_2)\Delta x + f(x_3)\Delta x + \ldots + f(x_n)\Delta x],$$

built up as follows: Divide the interval from a to b into n equal parts, and call each part Δx, $= (b - a)/n$; in each of these intervals take a value of x (say $x_1, x_2, \ldots x_n$), find the value of the function $f(x)$ at each of these points, and multiply it by Δx, the width of the interval; then take the limit of the sum of the terms thus formed, when the number of terms increases indefinitely, while each individual term approaches zero.

Geometrically, $\int_a^b f(x)dx$ is the area bounded by the curve $y = f(x)$, the x-axis, and the ordinates $x = a$ and $x = b$ (Fig. 8); that is, briefly, the "area under the curve, from a to b." The **fundamental theorem** for the evaluation of a definite integral is the following:

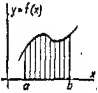

FIG. 8.

$$\int_a^b f(x)dx = \left[\int f(x)dx\right]_{x=b} - \left[\int f(x)dx\right]_{x=a};$$

that is, the definite integral is equal to the difference between two values of any one of the indefinite integrals of the function in question. In other words, the limit of a sum can be found whenever the function can be integrated.

Properties of Definite Integrals.

$$\int_a^b = -\int_b^a; \quad \int_a^c + \int_c^b = \int_a^b.$$

THE MEAN-VALUE THEOREM FOR INTEGRALS.

$$\int_a^b F(x)\, f(x)dx = F(X)\int_a^b f(x)dx,$$

provided $f(x)$ does not change sign from $x = a$ to $x = b$; here X is some (unknown) value of x intermediate between a and b.

THEOREM ON CHANGE OF VARIABLE. In evaluating $\int_{x=a}^{x=b} f(x)dx$, $f(x)dx$ may be replaced by its value in terms of a new variable t and dt, and $x = a$ and $x = b$ by the corresponding values of t, provided that throughout the interval the relation between x and t is a one-to-one correspondence (that is, to each value of x there corresponds one and only one value of t, and to each value of t there corresponds one and only one value of x).

DIFFERENTIATION WITH RESPECT TO THE UPPER LIMIT. If b is variable, then $\int^b f(x)dx$ is a function of b, whose derivative is

$$\frac{d}{db}\int_a^b f(x)dx = f(b).$$

DIFFERENTIATION WITH RESPECT TO A PARAMETER.

$$\frac{\partial}{\partial c}\int_a^b f(x,c)dx = \int_a^b \frac{\partial f(x,c)}{\partial c}dx.$$

Functions Defined by Definite Integrals. The following definite integrals have received special names, and their values have been tabulated; see, for example, B. O. Peirce's "Table of Integrals."

1. Elliptic integral of the first kind $= F(u, k) = \int_0^u \frac{dx}{\sqrt{1 - k^2 \sin^2 x}} (k^2 < 1)$

2. Elliptic integral of the second kind $= E(u, k) = \int_0^u \sqrt{1 - k^2 \sin^2 x}\, dx$ $(k^2 < 1)$

3, 4. Complete elliptic integrals of the first and second kinds; put $u = \pi/2$ in (1) and (2).

5. The Probability integral $= \frac{2}{\sqrt{\pi}}\int_0^x e^{-x^2}dx$

6. The Gamma function $= \Gamma(n) = \int_0^\infty x^{n-1}e^{-x}dx$

Approximate Methods of Integration. Mechanical Quadrature.

1. Use Simpson's rule. See p. 106, or, for greater accuracy, Weddle's Rule (see Scarborough, "Numerical Mathematical Analyses," p. 120, Johns Hopkins Press).

2. Expand the function in a converging power series, and integrate term by term.

3. Plot the area under the curve $y = f(x)$ from $x = a$ to $x = b$ on squared paper, and measure this area roughly by "counting squares," or more accurately, by the use of a planimeter, or by graphical means (see Fry, "Differential Equations," p. 69, Van Nostrand).

(4) Coradi's Mechanical Integraph ($240) provides a means of drawing on paper the curve $y = \int f(x)dx$, when the curve $y = f(x)$ is given, and can be used to facilitate the solution of certain differential equations. Full instructions for use with each instrument.

Double Integrals. The notation $\int\int f(x, y)dy\, dx$ means $\int \{\int f(x, y)dy\}dx$, the limits of integration in the inner, or first, integral being functions of x (or constants).

EXAMPLE. To find the weight of a plane area whose density, w, is variable, say $w = f(x, y)$. The weight of a typical element, $dx\, dy$, is $f(x, y)dx\, dy$. Keeping x and dx constant, and summing these elements from, say, $y = F_1(x)$ to $y = F_2(x)$, as determined by the shape of the boundary, the weight of a typical strip perpendicular to the x-axis is $dx\int_{y=F_1(x)}^{y=F_2(x)} f(x,y)dy$. Finally, summing these strips from, say, $x = a$ to $x = b$, the weight of the whole area is $\int_{x=a}^{x=b}\{dx\int_{y=F_1(x)}^{y=F_2(x)} f(x, y)dy\}$, or, briefly, $\int\int f(x, y)dy\, dx$.

Shell and coil (brine in coil), 2d coil	3.0
Double pipe	6–7
Superheat remover, shell and tube	15–25

Forced circulation of the air increases the coefficient to 1½ to 2½ times the values for still air. One inch of frost decreases the value 25 percent.

and 3 in. outer pipe. The commercial rating is 15 to 20 ft length of coil per ton of refrigeration.

The **shell-and-tube cooler** is used with closed heads and is erected both vertically and horizontally; brine flows through the tubes and ammonia is in the shell. It is made in sizes from 1 to 350 tons with ratings of 8 to 15 sq ft effective surface per ton, varying with the temperature and brine velocities; tubes 1 to 2½ in. arranged multipass. This type of cooler has largely displaced all other types in recent installations.

Piping of Rooms. The size of pipe usually employed for piping rooms varies from 1 to 2 in.

For ships' provision rooms and vessels having only small cargo compartments, the direct-expansion system is usually adopted, as the mains are generally short and fairly readily accessible; also the financial liability to the vessel for cargo damage is much less than for a large cargo vessel because of the lesser value of the cargo carried.

On the contrary, the total tonnage of large cargo vessels employing the brine-distribution system is many times greater than that of the vessels employing the direct-expansion system of distribution, despite the fact that the earliest of such vessels were equipped with direct-expansion cooling. The requirements of operating reliability are met much more nearly with this system. It can be used for varying compartment temperatures quite readily and is more flexible in operation and requires less skilled supervision. It is a necessity in case of the centrifugal system of refrigeration where the refrigerant cannot be circulated to the various cooling units throughout the vessel. Competent authorities claim that it is the only system ever to be used for large refrigerated-cargo vessels, this being based on extensive experience with each, where cargoes are carried below freezing temperatures.

The air-cooling coil surface will accumulate ice which must be regularly removed to maintain efficient cooling. This can be readily accomplished on the brine system by circulating warm brine in a simple reliable manner through the cooling coils. It can be accomplished with the direct-expansion system of distribution by circulating hot gas through the cooling coils, but on a large cargo vessel this is not simple to operate. It requires much additional pipe and many connections, all of which are additional refrigerant-leakage hazards.

Further, when in use, unless the operator is quite skilled, it can completely upset the operational efficiency of the plant and thereby be a hazard against the safe carrying of the cargo. When the machinery used is of the reciprocating type and the selected refrigerant is Freon, it is imperative that the lubricating oil for any one compressor be returned to that compressor at approximately the same rate as it leaves with the discharge gas. Freon and oil are miscible; therefore, oil carried over from the compressor with the discharge gas will pass from the condenser in solution with the liquid Freon. It will not be concentrated until this liquid is boiled off in the evaporator coils, but it can return with the suction gas to the compressor as a foam.

It is not desirable to have liquid slop over from the evaporator shell in order to facilitate the return of this oil automatically with the suction gas, and it is difficult to get it back otherwise, unless means, external to the evaporator, for superheating are used, especially when the evaporator is operating under a reduced rate of loading. Further, the long run of suction piping and the position of the compressors in relation to the evaporator coils tend to prevent the ready return of this oil, and operational unreliability may result. This can be overcome by skilled operators if they are available.

If the percentage of oil in solution is allowed to accumulate in the evaporator shell, its presence there will raise the evaporator temperature for any given suction pressure and so reduce its efficiency, in addition to making it necessary to add more new oil to the compressor manually. This oil-return characteristic makes it essential to operate only one compressor on any evaporator unit or group of evaporator units; *i.e.*, no two compressors can operate satisfactorily in parallel on any evaporator unit or group of evaporator units.

When direct-expansion coils are used to transfer heat directly to the air stream, to the refrigerated space, or to brine, the refrigerant is fed into the coil usually in a direction counter to the direction of air or brine flow and

The average heat transmission in cold-storage rooms without forced circulation of the air is about 2 Btu per sq ft of outside metal surface per hr per deg F temperature difference with horizontal piping and 2.5 Btu with vertical piping. When forced air circulation is used, the transmission rate will increase to 20 Btu or more. In **brine circulation**, the brine, with the same back pressure, has a higher temperature than the ammonia, and consequently 1 to 1½ times as much pipe is used in brine circulation as in direct expansion for a given back pressure.

The extra cost of liberal piping allowance will often be offset by the consequent improvement in the efficiency of operation of the compressor. An expansion valve should be provided for every 400 ft length of 1 in. pipe, every 500 ft of 1¼ in. pipe, and every 1,000 ft of 2 in. pipe.

Values of **over-all coefficients of heat transfer** in Btu per hour per square foot per degree Fahrenheit for refrigerating practice are given in Table 22.

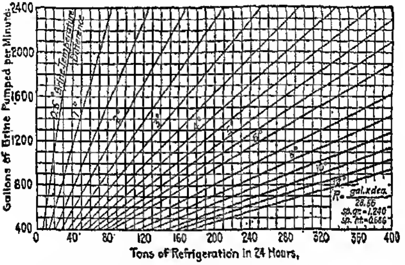

Fig. 5.—Refrigeration Produced by Brine.

Brine circulation is generally preferred to direct expansion, in consequence of the fear of danger from escaping ammonia or other refrigerant in case the pipes should leak. An advantage of the brine system is that there is always a considerable mass of refrigerated brine which can be drawn on in case the machinery should have to be stopped for any reason. In small plants, the general machinery may be stopped at night and only the brine pump be kept going to distribute the surplus refrigeration which has been accumulated in the brine during the day. Brine piping must consist of two lines, a flow and return, usually of the same size. Brine storage is seldom used because of its bulk, its first cost, and the practical inability to store much refrigeration. The modern automatic plant can handle the night load without difficulty.

The **cooling coils** in each refrigerator are in multiple with the supply and return pipes. It has been common practice to allow 120 to 150 running feet of 1¼ in. **pipe** per ton of refrigerating capacity in a **brine tank** for general refrigeration. The **tons refrigeration produced by brine** at various temperature differences and rates of pumping are given in Fig. 5.

distributed to the various coils by means of a distributor. As the liquid progresses through the coils, any oil accompanying the refrigerant is progressively concentrated as the refrigerant is evaporated. The final oil-refrigerant mixture leaving the coil has an amount of refrigerant absorbed in it which varies with the temperature-pressure condition. This mixture is quite homogenous in the form of foam. By properly dimensioning suction lines, this foam can be carried back to the compressor. This type of feeding is necessary in this type of application. This would not be strictly dry evaporation, and the heat-transfer coefficient on the refrigerant side is substantially the same as in the case of a flooded application, except that, as the refrigerant progresses through the coil, a considerable amount of surface is required for superheating the refrigerant. On this portion of the coil, the heat-transfer rate is quite low; therefore, external means of superheating are used as described below. This method is advantageous in that no oil is trapped anywhere beyond the condenser and the velocity of returning gaseous refrigerant sweeps the oil along with it and back to the compressor crankcase. However, when the loads are reduced, the distributor no longer functions so as to produce uniform feeding in all circuits nor does the necessary velocity exist to sweep the oil-Freon mixture, in the form of foam, back to the compressor.

Evaporators have been built having the refrigerant through the tubes and the brine through the shell. They work substantially as described above, but the indefinite distribution of refrigerant through respective feeds causes poor performance particularly at reduced capacity and, of course, poor performance means increased weight and space requirements. There is another point more definitely against this apparatus from a heat-transfer standpoint; namely, the change in evaporator temperature due to the pressure drop through individual feeds plus the liquid head penalty. This arrangement has never been satisfactory. Adequate brine velocity over tubes in the shell is more difficult of attainment than when the brine is fed through tubes.

Aside from the flooded brine cooler, where the refrigerant is in the shell and the brine is fed through the tubes, a type of evaporator often called **flash** or **spray** involves passing the brine through the tubes and spraying the refrigerant over the tubes by means of a refrigerant recirculating pump which takes its suction from the bottom of the brine-cooler shell and feeds it over the tubes through a distributing pipe. Oil return on this type of apparatus is accomplished by means of a still heated by discharge gas from the compressor, by electricity, or by other means. The liquid to be distilled is bled from the recirculating-pump discharge to the still and the resulting oil concentrate is returned to the compressor, the gas being returned to the suction line. This means of removing oil obviously entails a loss in refrigerating capacity, but the loss is so small that it can be neglected, being approximately 1 to 2 percent at most.

When flooded evaporators are used, it is necessary, as indicated above, to use means of superheating the refrigerant externally to the evaporator. The returning of oil from such an evaporator requires that a slight slop-over from the evaporator be maintained at all times, this liquid slop-over then being dried by superheating on the way to the compressor. Heat exchange between the high-pressure liquid line and the suction line is the usual method.

Float controls are not generally looked upon with favor when applied to marine brine coolers because of the pitch or roll of the ship. However, the same result may be accomplished by piloting the control valve with thermal expansion valves. Therefore, a direct-expansion evaporator does not necessarily always operate under conditions usually termed as dry evaporation.

Brine. Three kinds of brine have common use in refrigerating systems, sodium chloride (common salt), magnesium chloride, and calcium chloride. Calcium chloride is used most extensively because it is less corrosive and has a lower freezing point. It is supplied in 600 lb drums, either solid or granulated, and in tank cars containing 6,000, 8,000, or 10,000 gal of liquid at 1.350 sp gr. The properties of sodium chloride solutions are given in Table 23, of calcium chloride in Table 24, and of magnesium chloride in Table 25. Freezing points vary with the purity of the commercial salt and with contamination while in use. The Solvay Co. calcium chloride crystals are of approximately the following percentage composition: calcium chloride, 73.6; sodium chloride, 1.45; water, 24.9; constituents insoluble in water, 1.07. Table 26 gives the variation of specific gravity of brines with tempera-

In short, flooded evaporation is preferable on account of the equal division of load at reduced capacity and on account of the more effective use of heat-transfer surface.

NOTE. This oil discussion refers to Freon or other hydrocarbon refrigerants that are miscible with oil and not to NH_3 or CO_2.

To summarize, the most reliable operational results would be obtained by using the brine-distribution system.

Types of Cargo. The cargo to be carried under refrigeration comes under two major types which differ essentially in their treatment:

1. Frozen cargo, such as meat in bulk (sides or quarters) or in individual frozen cuts packed in cartons or other containers, as they are received from the packing house. Butter, fish, and many other food products.

These are usually carried at 15 F or lower and will pack well in bulk in deep holds or 'tween decks, depending on the type of container used, except bulk meat which will always carry well packed in bulk if properly battened for air circulation through the cargo and to prevent the cargo from resting directly upon the surface of the insulation.

This kind of cargo will carry well with refrigeration applied by means of forced air circulation, because the forced air movement over and through the cargo, together with the temperature rise in the circulated air, will have little or no drying effect on the cargo, and neither shrinkage by drying nor mold growth from moisture will damage the cargo in transit, if it has been loaded thoroughly frozen and surface dry.

2. Chilled cargo, such as chilled meat, eggs, cheese, fruit, vegetables, or other edible products (not frozen), delivered to the vessel in a precooled condition (not at field temperature), is usually carried somewhat above the congealing point, approximately 40 F.

This kind of cargo (except chilled beef) will carry well with forced air circulation, but care must be used to have an air inlet temperature to the cargo high enough to avoid freezing the cargo with which it comes in contact. The amount of air circulated to take up insulation leakage and any heat generated within the cargo, together with fan heat, must be sufficient to maintain a small differential between air temperature delivered to the cargo and that returning from the cargo.

In general, these chilled cargoes are not suitable for stowage in deep holds as the weight of such stowage is too heavy for the lower tiers of goods to withstand. It is essential that adequate air passages be provided for the circulated air through the cargo and between the face of the insulation and the body of the cargo. This is accomplished by the use of portable gratings on the deck surface, permanent battens on the insulation surface, and the use of portable separating battens between the layers of cargo stowage, if the cargo package is of a nature which will, in itself, not provide for adequate air passages between and around the packages.

This battened stowage is of particular importance in the case of some of these products, because they themselves give off heat during carriage when the ripening process must be allowed to continue slowly.

In bulk meat, the most desirable edible beef is carried chilled—not frozen—and a very close temperature range or variation through the cargo has been found necessary, especially if the refrigerated voyage is over 10 days' duration. In past experience, the temperature variation permitted has been between 29½ to 30½ F, or a range throughout the entire cargo of only 1 F. Further,

ture. Table 27 gives the weight of commercial calcium chloride required to make brine of a stated specific gravity.

The density of brine is measured by a salinometer (or salometer) which is a simple hydrometer the indications on which are 4 times greater than on the corresponding Baumé scale (see p. 86).

Table 25. Properties of Magnesium Chloride Solutions

It is undesirable to use a strength of solution of salt greater than is necessitated by its freezing temperature, as the specific heat (Tables 23, 24, and 25) decreases as the concentration of the brine increases, and consequently the stronger the brine, the less heat a given amount of it is able to convey between certain definite temperatures and the more power

Table 26. Specific Gravities of Brines

is required to pump the brine. Moreover, brine which is too strong may cause clogging of pipes, etc., by depositing salt. On the other hand, if the solution is too weak it may not be able to withstand the temperature existing in the expansion coil, so that a layer of thin ice will form around the latter and interfere with the absorption of heat from the brine. The surface of the expansion coils in the brine tank should be inspected from time to time

it has been found necessary to have the least possible drying effect from the air; hence, no appreciable air velocity over the cargo can be used.

These factors indicate that, as long as these requirements for the carriage of this cargo are imposed upon the vessel by the shipper, it will not be possible to use forced air circulation for the cooling medium; and the cooling medium will have to remain convection air currents as in the past.

Bulk meat was a most important cargo in prewar years between the United States and European ports and between South American and European ports. The latter trade has been most exacting as to its refrigeration requirements because of the length of the voyage (18 to 21 days) under refrigeration. If the freight rates are equitable, the trade should still continue to be desirable. The cargo is carried suspended from meat rails running fore and aft and fastened to the overhead deck spaced at 12-in. centers between the overhead pipes of the brine-cooling system. This piping is spaced on alternate 8- and 4-in. centers, with the meat rail between the 8-in. center brine-pipe runs. The sides and bulkheads are piped all over at about 6-in. centers. The beef is in quarters and is muslin-covered with hind quarters suspended from the shank, and the fore quarters from the flank, by galvanized meat hooks and chains with hooks to slip over the meat rails. The meat is tightly packed to resist motion from the vessel's movement in a seaway. Brine at about 25 F is circulated through the pipe system to cool the space, and the cargo comes aboard quite chilled. The height from the deck to the underside of the 1¼-in. pipe rail is from 6 ft 9 in. to 7 ft 0 in., and no greater height is of any use. Therefore, the molded deck height for such cargo can be about 8 ft 0 in., depending upon the depth of the deck beams and the resulting depth of the insulation below the overhead deck. This is also a suitable deck height for refrigerated cargo in general.

The deck from which this chilled cargo is suspended may also have a bulk or package cargo supported on its upper surface at the same time. The deck, therefore, requires special strength treatment.

The construction of an efficient refrigerated-cargo vessel requires special design treatment to handle mixed refrigerated cargoes economically. Such a vessel could have a deep hold and two deep 'tween decks and be insulated only by an external envelope (as is the case of the ships refrigerated by turbo-compression units mentioned above), which is entirely adequate for the type of cargo it is designed to carry.

A preferable design for a refrigerated-cargo vessel would be made around the general condition that the cargo does not lend itself to deep stowage and has to be generally stowed by hand and carefully handled. The hatchways need not be large for refrigerated cargo, though at least one hatchway may be long for loading general cargo on a nonrefrigerated voyage.

A nonrefrigerated vessel of 40 ft 6 in. molded depth at the side may have a hold 19 ft 6 in. deep at the center and two 'tween decks of 9 ft 0 in. height, these dimensions depending on camber and shear. If this same hull is to be arranged for refrigerated cargo throughout, it could have a hold 13 ft 6 in. deep and three 'tween decks of 8 ft 0 in. height, depending, as before, on camber and shear. The refrigerated hull should be equipped with comparatively small hatchways and have cargo-loading ports in the upper deck space on each side. Then if two of the hatchways were trunked through the three upper 'tween decks to the hold ceiling, facilities would exist for loading and discharging refrigerated cargo at intermediate ports and, by the subdivision of insulated spaces resulting from such a design, varying temperatures in these cargo compartments and hatchway spaces could be maintained. All

to see if any ice has formed on them. In larger plants, it is customary to use a solution with a freezing point not less than 10 deg below the lowest temperature which will be obtained in the operation of the plant. In smaller isolated plants and where careful supervision is not ensured, it is customary to make the solution as strong as possible without being unstable, usually 1.240 to 1.250 sp gr. Magnesium chloride is unstable at high concentrations and low temperatures. Its decomposition may result in corrosion. For a given temperature, the concentration is less than for the other brines. It is not used in large systems.

Table 27. Weight of Commercial Calcium Chloride in Brine

Spec grav.	1.10	1.12	1.14	1.16	1.18	1.20	1.22	1.24	1.26	1.28	1.30	1.32
Weight per gal, lb	1.41	1.70	2.00	2.30	2.59	2.90	3.20	3.50	3.83	4.13	4.46	4.78

Specific gravity is at 60 F for both brine and water. The weights are of 73 to 75 percent solid calcium chloride per gal of brine at 60 F. For flake 77 to 80 percent calcium chloride multiply the weights given by 0.94.

insulated spaces require adequate ratproofing the degree depending upon the type of insulation. All hatch coamings require heavy galvanized sheet-metal lining to protect them against cargo damage, particularly when loading a nonrefrigerated general cargo. All hatch plugs require similar metal treatment and should be constructed to be quite airtight and have overcovers to assist in this. They should also be protected at each deck level by the usual wooden hatch covers which would support the gratings for the cargo in the hatch wells. Where hatchways are trunked, the insulated doors to the compartments they serve should be well fitted with adjustable hinges and very substantial supports and fastenings. If double doors are used, they

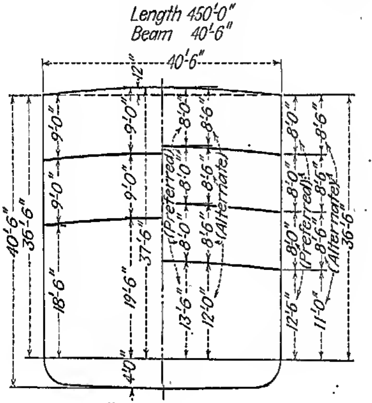

FIG. 3.

are more likely to remain tight if built with a portable center mullion, so that each door fits completely to its own aperture. All doors should open into the hatchway. All deck gratings should be in sections for easy removal for cleaning and should be constructed of finished lumber, shellac-coated, so that the space can be kept clean before loading. The bearers should be parallel to the direction of the designed air flow; they are usually athwartship with the slats fore and aft. Galvanized nails are used.

The fixed cargo battens on the face of the insulated surface should be arranged vertically and their corners mitered to guard against cargo damage. They keep the cargo from bearing on the insulation.

It is a designer's choice whether the designed air flow is from overhead down through the cargo, or from below the gratings upward through the cargo. Both systems have been used with success. A combination of these systems has also been used with success.

CARGO REFRIGERATION

BY

LLEWELLYN WILLIAMS

General. In general, refrigerated seagoing ships of the merchant marine are required to load and carry nonrefrigerated general cargo for a portion of their voyage from home port and on their return to home port, and a refrigerated cargo for some other part of this voyage. The vessel's cargo compartments and hatchways have, therefore, to be designed for the rapid and economical loading and discharging of these types of cargo. The whole vessel may be insulated and refrigerated throughout all its cargo spaces, or it may be subdivided so as to have some spaces available for general cargo only and the remainder equipped for refrigerated cargo. In either case it is economically desirable that the necessary deduction from the "bale" space available within the hull, for the insulation and refrigerating equipment and access thereto, be reduced to the minimum, since this deducted space shuts out both general and refrigerated cargo and thereby reduces the pay load that the vessel can handle.

Obviously, the weight of the refrigerating equipment and insulation should be kept as low as possible consistent with operational reliability, because this weight also reduces the pay load that the vessel can handle, particularly for that portion of the voyage when it is loaded with general cargo with a high weight per cubic measurement, such as steel rails.

As the United States is pretty much self-supporting for its food products, it is likely that our refrigerated vessels will be required to operate in a three-way manner; *i.e.*, they will load with American manufactured articles at their home port for the first leg of their foreign voyage; then, having discharged this cargo in foreign ports, they will load a refrigerated cargo for some densely populated country such as Europe or Asia; having discharged this cargo, they will load whatever cargo is available for import to the United States (generally much less than the vessel's carrying capacity) and will return home at least partly in ballast. Therefore, the greater the design stability of the vessel as a light ship, the less the ballast that will be required.

This requires that the refrigerating machinery be placed as far below the center of buoyancy as possible; and, to save loss of space and to simplify operational supervision, it is very desirable to have the refrigerating machines located within the main engine room and on the lower platform. This qualifies the necessity for a safe refrigerant applied to small space, lightweight refrigeration machines operating at high rotating speeds, and the use of a minimum number of such machine units consistent with reliable operation.

In the case of vessels using brine circulation as the means of distributing cold to the various cargo spaces, it will be desirable to locate the brine coolers (evaporators) and their pumps within an insulated space immediately adjacent to or as a part of the shaft tunnel abaft the engine room. The pump motors can be arranged in the main engine room with shafts extended through bulkhead stuffing boxes to the pumps located in the insulated brine-cooler space. The refrigerant condensers and their sea-water circulating pumps should be arranged within the main engine room. Thus the entire

The heat flow through the insulation is from the hot side to the cold side; therefore, heat entering the compartment first contacts the boundary air on the inner surface of the insulation and, if it is not immediately taken up by the stream of circulated air, will heat up the immediately adjacent cargo and perhaps damage it. Therefore, the air circulation should be directed to the removal of this heat.

Air-cooling Units. The air-cooling units, whether designed for brine-distribution or for direct-expansion distribution, can be completely factory-assembled units, each, when vertical, consisting of a galvanized metal lower coil section containing the cooling coils, and an upper fan section containing the fans, bearings, and an externally fitted motor for driving the fans. The fan drive can be either direct-connected or through V-belts with suitable arrangements for belt adjustment. This is the preferred system. The fans should, in general, be adequate for an air flow of one change per minute of total cargo-capacity air and have variable fan speeds or dampers, which will permit the air flow to be reduced to half the above. In some cases of chilled cargo, the maximum air flow above may need to be increased to conform to the permissible temperature rise in the air when balanced against the heat load. In handling frozen cargoes, a change of air every two minutes will be ample, and the heat imparted to the air by the fan will be reduced. In carrying chilled fruit, ample air is necessary for thorough ventilation of the cargo.

Some outside fresh air is desirable in handling fruit cargoes, but this air should be introduced over the coils, so that its surplus moisture will be deposited upon the cold surface of the coil and not upon the cold surface of the cargo. It is preferable to accomplish this by exhausting air from the end of the cargo space remote from the cooling unit and through separate ventilation openings. These openings should be fitted with insulated plugs so that they can be completely shut off when not in use. Some chilled cargoes, particularly apples, require a close regulation of this ventilating air for the whole voyage. The fruit gives off CO_2 gas very rapidly when being cooled down and the concentration should not be permitted to exceed 12 percent. The gas comes off at a greatly reduced rate after the fruit is cooled down, and it has been found desirable to have a permanent concentration of some 10 percent CO_2 gas to cut down fruit scald in transit.

In general, a provision of 5 percent of the total circulated air as fresh air for ventilating purposes will be ample; and the less that can be found practical for satisfactory use the better. Before loading a refrigerated cargo, all spaces should be thoroughly cleaned and the space cooled down to approximately the carrying temperature before loading. During loading, it is desirable to operate the fans continuously, but at their lowest air flow. When any compartment has been loaded, the air flow should be increased to conform to the temperatures required. The whole fan unit, including the coils, casing, and wheels, should be galvanized or tinned to guard against corrosion. All bearings should have suitable covered access openings. A suitable trapped scupper should be fitted to the drain pan and arranged for easy cleaning.

All refrigerant-flow-control devices and air-flow-control devices should be arranged outside the air stream. The cooling unit, as a whole, should always be outside the cargo space with suitable guarded air openings for the air flow from the cargo space to the unit and from the unit to the air-distributing duct system of the compartment. Large compartments should be protected by duplicate cooling units dividing the cooling load.

cold-producing portion of the refrigerating machinery plant will be immediately accessible to the main engine-operating staff, and their weight will be as far as possible below the center of buoyancy and will, in addition, cut out the least possible pay load.

In the choice of a refrigerant it is necessary or desirable to use one that can be readily obtained in any important foreign port as the value of refrigerated cargo (insured) is too high to rely for its safe carriage on having a "spare charge" aboard. This spare charge is a valuable asset but is not a guarantee that the cargo cannot be lost because the use of some special refrigerant, not in general use commercially, has been adopted for the plant. Further, in the interest of safe cargo carriage, it is desirable, on *refrigerated-cargo ships*, that the compression plant be subdivided into at least two parts (one spare), that these two plants be completely disconnected from each other in normal operation, and that only breakdown means for cross-connecting them be furnished with the vessel's spares.

By far the greater portion of refrigerated tonnage now in service uses CO_2 (carbonic anhydride) as its refrigerant, chiefly because it is generally recognized as safe and is universally procurable, since it is used for many commercial purposes other than refrigeration, besides being one of the oldest refrigerants in general use. Its chief disadvantages are its high operating pressures, high power requirements, and the large space and weight requirements of its condensers and evaporators.

The Freon refrigerants are comparatively new and, although they are universally used on U.S. refrigerated vessels, they are almost entirely "war-built" and form a relatively small percentage of the refrigerated-cargo space in use. These Freon refrigerants are easily the most desirable if they can be readily obtained in foreign ports.

Freon 12 is in general use in the United States for reciprocating-type machines, with the new Freon 22 threatening to displace its older brother, especially where low temperatures are desired. Freon 11 is the refrigerant generally adopted in U.S. refrigerated ships using the centrifugal type of refrigerating machine, and there are some large refrigerated-cargo U.S. ships which have been in satisfactory service through the tropics. More similar vessels are being built, each of which has approximately 350,000 cu ft insulated space available for refrigerated cargo of frozen meat carried at 15 F. Leakage of all the Freons is not easily detected.

When the refrigerated-cargo vessel has no passenger space and the refrigeration machinery can be located in a deckhouse, apart from the main engine room and navigation quarters, and can be adequately ventilated safely, anhydrous ammonia is a very desirable refrigerant. It is not a safe refrigerant, being highly noxious and, under certain conditions, both flammable and explosive. However, leaks in the system can be very easily located, and its operating pressures are reasonable, its power requirements low, its machinery weight also reasonable, but its weight would, of ventilation necessity, be located much above the vessel's center of buoyancy. It is universally readily procurable. New vessels being refrigerated in Great Britain are using it as the refrigerant.

As the choice of a refrigerant is so important for a cargo vessel, it might be desirable to summarize as follows:

First choice: For reciprocating-type machines, Freon 12 or Freon 22 whichever is the more readily procurable.

Second choice: For reciprocating-type machines, CO_2 (carbonic anhydride).

Third choice: For reciprocating-type machines, NH_3 (ammonia).

The cooling unit referred to is one in which the air is drawn over the cooling coils by the fans and discharged directly to the cargo space through the distributing duct system. In this case, the heat added by the fan losses raises the temperature of the air, reduces its relative humidity and, therefore, promotes the drying of the cargo by the circulated air. This is not of importance in the case of frozen cargo or completely enclosed package goods, but it is a detriment in the case of chilled-fruit cargoes, especially those carried in bulk or not paper-wrapped and in open slotted boxes. For such cargoes, it is very desirable to have the air drawn from the cargo space and then blown over the coils to the duct system so that the fan heat is taken up immediately by the cooling coil, and the drying effect on the cargo can be greatly reduced. This can easily be obtained if the unit is so constructed at the factory. Where the units required are too large for factory assembly, they may be fabricated in the ship from factory-assembled parts. This can also be done with smaller units if factory-assembled units are not available.

Where a vessel is trading through cold waters or discharging in cold climates, it may be quite desirable to fit a means of heating the air to each unit. This is also very useful in warming up and drying out the refrigerated compartments before general cargo is loaded and after the refrigerated cargo has been discharged. This can be done quite easily when a brine-distribution system has been adopted, and the brine heater normally installed for coil defrosting has been made large enough to furnish the heating requirements of the cargo spaces.

If the direct-expansion system of distribution is adopted, it will be necessary to fit each air-cooling unit with a heater. If electrical power is available, it would be the preferable method because it would then not be necessary to guard against freezing of the heating fluid when the heater was not in use, as would be the case with any other convenient methods.

Extreme care should be used to protect all electrical devices used against the action of sea air and the sweating that results in refrigerated compartments due to changes in temperature when a refrigerated cargo is being discharged or when a general cargo is being handled after the refrigerated cargo has been discharged. A desirable arrangement would be to center all electrical controls in the machinery space or in substations completely separated from the refrigerated cargo spaces and open to or ventilated from the outside air. Where large cooling units are fitted, this can be done readily by having the fan motors and their belt drive arranged in an access space insulated from the cargo space, and by locating all the controls in this space which would be ventilated from outside to remove the heat of the motor windings. Many vessels engaged in the fruit trade have used this method for years with complete satisfaction. Considering that the satsifactory carriage of a large amount of high-value cargo may depend upon the continuous operation of a 5-hp motor, it is obvious that the said motor should be installed so that it can be readily replaced at sea and in a position and manner which would subject it to the least risk against unsatisfactory operation.

Completely reliable temperature-indicating devices should be furnished and located where they are always readily accessible to the chief engineer and his staff. There should be at least one such connection for each compartment and, when air circulation is used, the temperature-sensitive member can be located in the return air stream, preferably in the fan chamber where it is easily accessible.

However, rugged and tested cased thermometers should always be provided, permanently mounted in the fan chamber and guarded against potential

The choice between centrifugal- and reciprocating-type machines is not simple as there are many conflicting characteristics of each to be considered. If the tonnage of each of the two machine units necessary as a minimum is not less than 120 at full power—which would be suitable for a vessel of from 250,000 to 300,000 cu ft of insulated space available for cargo—then the centrifugal equipment would be preferable if it is desirable to operate it by a direct-connected steam turbine without a speed-increasing gear box. When considered with its necessary steam condenser, vacuum-producing jet apparatus, and condensate pumps and because of the fact that it must be arranged in close-coupled form with its evaporator, refrigerant condenser, and steam condenser, both its weight and space requirements would probably be greater than for the reciprocating type and might well prevent its location within the main engine-room space and below the center of buoyancy of the hull. It cannot, at present, be economically produced for tonnages less than 120 full load in tropical waters. Such a compression unit in a refrigerated-cargo ship would be required to unload down to 25 percent capacity for continuous operation (say 30 tons output), after the cargo was at the desired temperature and the vessel still in tropical waters.

The centrifugal type is not positive in action, *i.e.*, it can operate and do no useful work, but it is easily and reliably operatable under extreme conditions by skilled, experienced personnel. However, it cannot be readily repaired on the voyage as the assembly work has to be very accurately executed. Vessels so equipped have given no serious trouble, but they must have experienced operators.

The reciprocating type of machine is positive in action, can be driven by a steam turbine through the medium of a speed-reducing gear box, can be produced in small or large size, can be readily unloaded, can be readily repaired during the voyage with spare parts, and is easy to operate efficiently by unskilled help. It requires slightly more power than the centrifugal and, of course, has many more parts subject to wear and breakage than the centrifugal, but it is more readily overhauled and repaired on the voyage or in foreign ports.

Both types can be operated by electric motor. The centrifugal type requires a speed-increasing gear box, and the reciprocating type can be direct-connected to its motor or driven through V-belts. If electrically driven, each type should have variable-speed characteristics built into the electric motor, which on shipboard is almost entirely d-c, 230-volt.

Distribution of Cooling Medium. The refrigerating plant produces liquid refrigerant or cold brine for distribution to the cargo-cooling mechanisms, which of necessity are arranged within the cargo spaces to be cooled. This distribution system is a very essential part of the over-all cooling system and should be designed in its simplest possible form to avoid troublesome operation and losses due to possible part failures.

The cooling units located within the cold spaces must have control devices readily accessible at all times.

The refrigerant itself can be distributed throughout the vessel from the central machine system to the cooling units and is then termed a **direct-expansion system of cooling.** The liquid refrigerant from the machine condenser system is piped throughout the vessel to each and every air-cooling unit in the cargo spaces. There it is expanded through suitable flow-regulating and protective devices to the air-cooling coils within each unit, where it is evaporated by extracting heat from the surrounding air

damage. There should be one for the return air and one for the delivery air, both readily accessible.

In cases where the shipper compels the vessel to hold very close temperature regulation as a part of the loading contract, it would be desirable that a temperature-recording device be also available for the observation of the chief engineer. This is especially true when a shipper places his own locked and sealed temperature recorder in the cargo space among the cargo, to be opened and examined when the cargo is being discharged. This has frequently been done with some cargoes, particularly with chilled beef.

If the heat removal method adopted is by direct expansion, the cooling coil should be entirely of nonferrous material and should be hot-tinned after coil assembly at the factory. This is to guard against internal corrosion of the coil and its control devices owing to water inadvertently getting into the refrigerant in the case of Freon.

Temperatures Required. Frozen cargoes are usually carried at 15 F or lower, when in bulk. In the future there will be large cargo offerings of quick-frozen cuts, *i.e.*, meat quick-frozen in the packing houses in cuts of varying weights for distribution to the consumer in the same condition as when shipped. These will be wrapped and packed in cartons. Similar packs of fish, fruit, and vegetable products will be shipped. The temperature required by the shipper will be low—probably around 0 F or even lower if such temperatures can be provided by the ship. Air circulation will be satisfactory for this type of cargo.

Chilled cargoes will require temperatures varying between 33 and 45 F, all requiring the control of relative humidities of the return air; therefore, the average relative humidity of the cargo space will be not less than 85 percent with 90 percent preferred. Lower relative humidities produce greater cargo-weight shrinkage and loss of product quality, whereas higher relative humidities can result in mold growth on parts of the cargo. The greatest hazard against the ship in the satisfactory carriage of such cargo is its being damp on the surface when being loaded. The vessel's personnel should make close inspection when such cargoes are being loaded, and they should also see to it that the cargo is properly packed and adequately dunnaged for air circulation. Insurance claims against the cargo by the shipper will result unless extreme care is exercised in loading. This is especially important because many honest stevedores are quite inexperienced in handling refrigerated cargo.

Refrigerating Tonnage. It is essential that the vessel be fitted with ample total refrigerating power, including spare power, for carrying cargoes through tropical climates and for loading cargoes in tropical ports, such as India, East Africa, North Australia, the East and West Indies.

It is simple to calculate the heat-leakage load by the usual heat-flow formula, using published values for the insulation materials to be used. However, when this has been done, the actual heat leakage will be found to be about twice as much as the calculation indicates, because the steel shell construction of the vessel is such that conventional calculation does not make due allowance for the varying heat-flow conditions as they actually exist.

Empirical heat-transfer rates as listed below can be used for any type of conventional insulation, such as is described below, used to enclose the space for refrigerated cargo. These rates cover the total heat leakage, and the summation will then approximate the actual heat leakage that will result

stream and then returned to the compression machines as suction gas for compression and liquefaction in the condenser system for recirculation through the closed system.

On a large cargo vessel this requires a complicated pipe system which should be accessible to the operating engineers for maintenance and repair. The pipe joints in such a system on shipboard are more vulnerable to leakage of refrigerant than on a corresponding land installation of similar size, because of the hull vibration, ever-present when operating at sea, and the necessity for tight-stowed cargo which renders accessibility extremely difficult where the pipes have to pass through cargo spaces and intervening watertight bulkheads. The refrigerant flow devices require numerous flanged joints which are always potential refrigerant leakers.

The direct-expansion system of distribution, however, is most attractive from a consideration of total weight and over-all operating power as no pumps are required to circulate the refrigerant. It is also very convenient

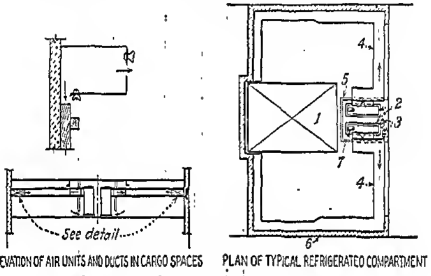

FIG. 1.—Typical refrigerated compartment showing air unit and duct arrangement.

for carrying widely varying temperatures in the several cargo compartments, as may be necessary with mixed cargoes. However, it does require more skilled operation to keep it in adjustment than the cold brine-distribution system.

The other method of cold distribution is the **brine-distribution system**, in which the refrigerating plant in addition to the machines, condensers, and liquid-storage receivers (common to each system) has brine coolers, in which the evaporating liquid cools a calcium chloride brine to the desired temperature, which is circulated by pumps and a pipe system to the various cooling units in the holds. Therefore, the brine coolers (there should be two for safety, one for stand-by in case of trouble), the brine pumps, and their motors add weight and require space in a vessel in excess of that required by the direct-expansion system.

The control at the air-cooling units is very simple and reliable, being merely flow-control valves which can be operated manually or automatically. The pipe lines can be fully welded and are not liable to leakage to the same extent as the lines carrying the refrigerant. In the case of a local fire there is

in practice. The heat flow per square foot of external surface per day per degree Fahrenheit difference in temperature is taken as

	Btu/(Day) (Deg F)
Area of upper deck surface exposed to sun (less hatches)	4
Area of hatches exposed to sun temperature	5
Area of ship's sides, tank tops, and bulkheads[a]	3
Area of all intermediate deck hatches	4

[a] If the ship is only partly insulated, this area should include intermediate decks adjacent to nonrefrigerated compartments.

The external temperatures are assumed to be

	Deg F
Top deck and hatches exposed to sun	120
Shell above water line	100
Shell below water line	90
Engine-room and boiler-room bulkheads	120

All deck and bulkhead ribbands are to be taken as additional hull areas.

Load calculations of the refrigerating requirements can vary quite widely, and the usual means of estimating heat loads as applied to land practice are insufficient for shipwork for several reasons:

1. There are extreme climatic changes and most frequently ships pass through the tropics—a fact that would require a design compatible with tropical conditions.

2. The insulation used in a steel ship hull is difficult to apply on account of structural conditions within the ship. For example, where the deck or bulkhead joins the ship's sides there is a heat path created which will increase heat losses. This is combated by the use of insulation, known as **ribbands**, extending inboard from the hull along the bulkhead or deck. Also, the hull insulation extends only a few inches inside the hull channels or frames (ribs).

3. Changing temperature causes the insulation to breathe, and it can very easily become saturated with moisture. Deterioration of insulation results.

4. The normal heat-transfer values for insulation do not generally apply because a certain portion of the ship is below water and subject to the heat-transfer coefficient of steel to water rather than steel to air as in the case of land practice.

5. The area of a ship's sides and top exposed to the sun is large in proportion to the volume contained and can easily become substantial. The upper deck exposed to sun and wind is frequently covered with a canopy when passing through the tropics to reduce heat leakage.

6. Many parts of refrigerated holds are subject to engine-room heat which at times may become quite high.

Heat-transfer factors for estimating the leakage load based upon actual practice have been given above. It is possible to arrive at a fairly accurate rule of thumb by dividing the stowage volume of a vessel by the tons of refrigeration installed so as to determine the cubic feet of stowage available per ton. This provides a rough check on heat leakage and at the same time presents a key to good commercial practice or a check on individual calculations. The factors are listed below and have been confirmed.

added hazard due to the brine; however, there can be a very serious added zard if the pipe lines carry the refrigerant. The brine flow can be comtely controlled from the central operating system and is usually so fitted

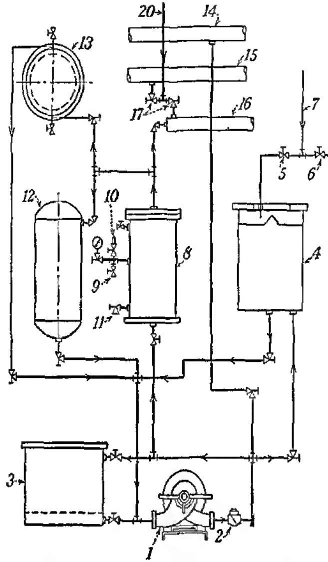

FIG. 2.—Schematic arrangement of warm brine piping. 1, Hot-brine pump; 2, check valve; 3, brine mixing tank; 4, hot brine return tank; 5, hot brine return valve; 6, cold brine return valve; 7, thirty-two hot or cold brine return lines from air-cooling coils; 8, brine heater; 9, steam inlet to heater; 10, relief valve; 11, condensate outlet; 12, brine storage tank; 13, brine cooler brine box; 14, brine main—from cold brine pump to cooler; 15, brine header—cold brine to coils; 16, hot brine header; 17, brine supply control valves; 20, hot or cold brine supply lines to air unit coils.

on either an open or a closed brine system. With this type of distribution system it is easier to prevent refrigerant leakage as all the refrigerant-carrying piping is within the operating space and is readily accessible at all times.

Insulation. Another reason why heat-transfer factors through insulation may vary widely is because the actual heat flow into the ship is a function of how the insulation is finally applied and what it is actually like having been in service. In view of this the American Bureau of Shipping makes an inspection of the insulation and machinery installation. The ship is cooled empty to a specified temperature and the temperature rise after six hours with machinery shut off is noted. The insulation value is then relative. Insulation is considered satisfactory if the temperature rise averages not more than ¾ deg per hr; however, more than this is allowed when the ship is classified. A typical method of insulation consists of four layers of rock-wool battens (Eagle Picher or Johns-Manville) between the ship's "ribs" with two layers of tongue-and-grooved boarding and paper, the latter covered with waterproofed plywood. The specification for such insulation reads in detail as follows. This is accepted as good practice.

All steel work behind insulation in refrigerated cargo spaces shall be thoroughly cleaned and given two coats of bituminous solution and one coat of enamel, applied hot, to a minimum thickness of 1/16 inch on vertical surfaces, and ⅛ inch on horizontal surfaces.

Insulation of the tank top shall consist of a 12 in. thickness of wooden grounds, laid in "grill" formation, spaced 18 in. centers, with all spaces completely filled with "insulation material." The bottom grounds shall be bolted to ¼ in. flat bars welded to the deck. Ends shall be adequately connected to each other. In addition, there shall be an adequate connection of grounds at crossings at sufficiently frequent intervals to prevent "tripping" and to reinforce each "layer" against lateral movement.

Insulation of boundary bulkheads and shell shall consist of "insulating material," applied to a minimum thickness of 12 in.; but completely filling the space between wood furring and steel plating. Adequate support shall be provided to prevent settling of insulation. The wood furring shall be of suitable thickness, bolted to ¼ in. flat bar clips welded to steel structure where bulkheads are flush or to the webs of frames and stiffeners and extending at least 2 in. inboard of inner edge of same. The lower ends shall be bolted to the grounds for the tank top or ribbands and the upper ends to the furring on the deckhead or the deck structure.

Insulation of deckhead under shelter deck shall consist of wood furring, fastened to the web of deck beams by screws or bolts, with spaces between completely filled with "insulating material," to the required thickness.

No insulation will be required on the underside or topside of 'tween decks, excepting for a three-foot ribband at shell and bulkheads, nor will insulation be required on intermediate bulkheads excepting for ribbands. Johns-Manville BX-18, or equal, shall be used for topside deck ribbands.

Adjacent decks for extent of 3 ft outside refrigerated spaces shall be fitted with 2 in. of Johns-Manville BX-18, or equal. Bulkheads and decks adjacent to machinery spaces shall be insulated on the machinery space side with at least 3 in. of approved insulation, and it shall extend for at least 3 ft beyond the refrigerated spaces. Ducts exterior to refrigerated cargo spaces and serving same shall be covered with insulation, 2 to 4 in. thick.

The tank top insulation shall be covered with 1½ in. of concrete, reinforced with 18-gage expanded metal. Over this shall be laid 1 in. of mastic composition coved up all around. It shall be compounded especially for use in refrigerated spaces for a range of 10 to 100 F. Gratings of wood, total height of 3¼ in., shall be fitted on the decks of all compartments and arranged in panels for easy removal. They shall be of spruce, with sleepers 1¾ by 3¾ in., top 1¾ in. thick by 4½ in. wide, and have ⅜ in. between boards. Top of grating boards shall be chamfered on each edge about ¼ in.

Sides and deckhead insulation shall be sheathed with two layers ⅞ in. T & G spruce, nailed to furring. There shall be two layers of 15-lb asphalt-saturated felt paper, one separating the two layers of T & G sheathing, one separating the T & G sheathing from the insulating material. Wood battens, 2 in., spaced 15 in. on centers, shall be nailed to the sheathing except in way of the coils.

DIFFERENTIAL EQUATIONS

An ordinary differential equation is one which contains a single independent variable, or argument, and a single dependent variable, or function, with its derivatives of various orders. **A partial differential equation** is one which contains a function of several independent variables, and its partial derivatives of various orders. The order of a differential equation is the order of the highest derivative which occurs in it. A solution of a differential equation is any relation between the variables, which, when substituted in the given equation, will satisfy it. The general solution of an ordinary differential equation of the nth order will contain n arbitrary constants. A differential equation is usually said to be solved when the problem is reduced to a simple quadrature, that is, an integration of the form $y = \int f(x)dx$.

Methods of Solving Ordinary Differential Equations

Differential Equations of the First Order

(1) If possible, separate the variables; that is, collect all the x's and dx on one side, and all the y's and dy on the other side; then integrate both sides, and add the constant of integration.

(2) If the equation is homogeneous in x and y, the value of dy/dx in terms of x and y will be of the form $\dfrac{dy}{dx} = f\left(\dfrac{y}{x}\right)$. Substituting $y = xt$ will enable the variables to be separated. Solution: $\log_e x = \displaystyle\int \frac{dt}{f(t) - t} + C.$

(3) The expression $f(x,y)dx + F(x,y)dy$ is an *exact differential* if $\dfrac{\partial f(x,y)}{\partial y} = \dfrac{\partial F(x,y)}{\partial x} (= P,$ say). In this case the solution of $f(x,y)dx + F(x,y)dy = 0$ is

$$\int f(x,y)dx + \int [F(x,y) - \int P dx]dy = C$$

or

$$\int F(x,y)dy + \int [f(x,y) - \int P dy]dx = C$$

(4) Linear differential equation of the first order: $\dfrac{dy}{dx} + f(x)\cdot y = F(x)$.

Solution: $y = e^{-P}\left\{\int e^{P}F(x)dx + C\right\}$, where $P = \int f(x)dx$.

(5) Bernoulli's equation: $\dfrac{dy}{dx} + f(x)\cdot y = F(x)\cdot y^n$. Substituting $y^{1-n} = v$ gives $\dfrac{dv}{dx} + (1 - n)f(x)\cdot v = (1 - n)F(x)$, which is linear in v and x.

(6) Clairaut's equation: $y = xp + f(p)$, where $p = dy/dx$. The solution consists of the family of lines given by $y = Cx + f(C)$, where C is any constant, together with the curve obtained by eliminating p between the equations $y = xp + f(p)$ and $x + f'(p) = 0$, where $f'(p)$ is the derivative of $f(p)$.

Differential Equations of the Second Order

(7) $\dfrac{d^2y}{dx^2} = -n^2y$. Solution: $y = C_1 \sin (nx + C_2)$

or $y = C_3 \sin nx + C_4 \cos nx$

(8) $\frac{d^2y}{dx^2} = +n^2y$. Solution: $y = C_1 \sinh (nx + C_2)$

or $y = C_3 e^{nx} + C_4 e^{-nx}$

(9) $\frac{d^2y}{dx^2} = f(y)$. Solution: $x = \int \frac{dy}{\sqrt{C_1 + 2P}} + C_2$, where $P = \int f(y)\, dy$.

(10) $\frac{d^2y}{dx^2} = f(x)$. Solution: $y = \int P dx + C_1 x + C_2$, where $P = \int f(x) dx$

or $y = xP - \int x f(x) dx + C_1 x + C_2$

(11) $\frac{d^2y}{dx^2} = f\left(\frac{dy}{dx}\right)$. Putting $\frac{dy}{dx} = z$, $\frac{d^2y}{dx^2} = \frac{dz}{dx}$, $x = \int \frac{dz}{f(z)} + C_1$ and $y = \int \frac{z dz}{f(z)} + C_2$; then eliminate z from these two equations.

(12) The equation for damped vibration: $\frac{d^2y}{dx^2} + 2b\frac{dy}{dx} + a^2y = 0$.

Case I. If $a^2 - b^2 > 0$, let $m = \sqrt{a^2 - b^2}$. Solution:

$y = C_1 e^{-bx} \sin (mx + C_2)$ or $y = e^{-bx}[C_3 \sin (mx) + C_4 \cos (mx)]$

Case II. If $a^2 - b^2 = 0$, solution is $y = e^{-bx}[C_1 + C_2 x]$.

Case III. If $a^2 - b^2 < 0$, let $n = \sqrt{b^2 - a^2}$. Solution:

$y = C_1 e^{-bx} \sinh (nx + C_2)$ or $y = C_3 e^{-(b+n)x} + C_4 e^{-(b-n)x}$

(13) $\frac{d^2y}{dx^2} + 2b\frac{dy}{dx} + a^2y = c$. Solution: $y = \frac{c}{a^2} + y_1$, where y_1 = the solution of the corresponding equation with second member zero [see (12) above].

(14) $\frac{d^2y}{dx^2} + 2b\frac{dy}{dx} + a^2y = c \sin(kx)$. Solution:

$y = R \sin(kx - S) + y_1$, where $R = c/\sqrt{(a^2 - k^2)^2 + 4b^2k^2}$,

$\tan S = \frac{2bk}{a^2 - k^2}$, and y_1 = the solution of the corresponding equation with second member zero [see (12) above].

(15) $\frac{d^2y}{dx^2} + 2b\frac{dy}{dx} + a^2y = f(x)$. Solution: $y = y_0 + y_1$, where y_0 = any particular solution of the given equation, and y_1 = the general solution of the corresponding equation with second member zero [see (12) above].

If $b^2 > a^2$, $y_0 = \frac{1}{2\sqrt{b^2 - a^2}} \left\{ e^{m_1 x} \int e^{-m_1 x} f(x) dx - e^{m_2 x} \int e^{-m_2 x} f(x) dx \right\}$,

where $m_1 = -b + \sqrt{b^2 - a^2}$ and $m_2 = -b - \sqrt{b^2 - a^2}$.

If $b^2 < a^2$, let $m = \sqrt{a^2 - b^2}$; then $y_0 =$

$\frac{1}{m} e^{-bx} \left\{ \sin (mx) \int e^{bx} \cos (mx) \cdot f(x) dx - \cos (mx) \int e^{bx} \sin (mx) \cdot f(x)\, dx \right\}$.

If $b^2 = a^2$, $y_0 = e^{-bx} \left\{ x \int e^{bx} f(x)\, dx - \int x \cdot e^{bx} f(x)\, dx \right\}$.

At least two "breather" plugs shall be fitted in each wall of each compartment as directed, consisting essentially of a ¾-in. shoulder bushing with a 100-mesh screen soldered in and arranged to screw into a threaded fitting in the sheating and readily replaceable with a plug.

In order to obtain the total heat load for the machinery, add to these calculated heat-leakage loads, the heat represented by the horsepower of all the fans, and the horsepower of the brine-circulating pumps (if brine distribution is used) together with an allowance for cooling down the cargo when received precooled but not received at the holding temperature. An allowance of 10 deg cooling in 48 hr for the whole cargo will be safe.

The summation of these items would represent the total refrigerated load and, if no complete spare unit is provided, the load which is estimated as a 24-hr load should have machinery available to absorb it in 18 hr of operation when sailing in tropical waters. Thus, if the summation amounted to 180 tons, then $180 \times {}^{24}\!/_{18} = 240$ tons refrigeration capacity would be provided by two 120-ton, three 80-ton, or four 60-ton machines. However, it would be necessary to have all the parts of these machines interchangeable and, in addition, carry a large complement of spare parts, to provide means of maintaining the operational efficiency of the equipment during the period of estimated shutdown. If two 240-ton machines were installed, either of which could absorb the heat load in 18 hr continuous operation, it is not necessary to carry extensive spares, but all parts of the machines should be interchangeable; and a fairly generous lot of spares should be carried.

In the event of the machinery being selected on the basis of 18-hr operation, the condensers, coolers, pipes, pumps, and all should be supplied to the full power of the machines, *i.e.*, 240 tons.

As the cargoes carried are very valuable and are always insured, the underwriters and classification societies will undoubtedly require the duplicate plant equipment, arranged as two completely separate units completely disconnected on the refrigerant side but common on the brine side.

As clearly stated, the above tonnages are not adequate for the carriage of cargoes not precooled, such as fruits loaded at field temperatures—bananas, for instance. These require quite special consideration, not only as to providing adequate machine capacity but also as to the stowage of the fruit, method of air circulation, etc.

The tonnage requirements as indicated from the calculations above referred to can be checked for any vessel by an examination of the ratio of insulated cubic capacity to refrigerating machinery tonnage as fitted to refrigerated-cargo vessels in the past. These figures can be obtained from Lloyd's register records of refrigerated ships. These records distinguish between vessels only partly refrigerated and having less than 80,000 cu ft insulated space and vessels wholly refrigerated or having insulated capacities of over 80,000 cu ft. From these records the following figures are found:

Twelve U.S. ships built 1918–1919, Lloyd's records 1924–1925, aggregate cubic capacity 3,420,000 ft, average per ship 285,000 cu ft. Total refrigerating-machine capacity 1,224 U.S. tons and average machine loading 2,790 cu ft per ton machine capacity. These machines all used CO_2 as the refrigerant and brine as the cold distribution medium, with all compartments fitted with brine piping distributed overhead and on all sides and bulkheads, and in hatchways. There was no forced air circulation used.

In the following list of ships from Lloyd's records, all machine tonnages have been reduced to U.S. tons, one ton being 12,000 Btu per hr between 0 F

Sales of Fractional Interests in Patents. Undivided fractions or territorial divisions of patent rights are advisable only in special cases, because with the best intentions the interests of joint or territorial owners are *liable to interfere.*

Licenses are permissions by the patentee to make, use, or sell the thing patented, and, broadly speaking, a license may carry any imaginable provisions the parties agree on, subject to certain restrictions upon agreements in restraint of trade, upon fixing resale prices, upon limiting the use of patented articles after their sale, and other restrictions of like character, as to which a lawyer should be consulted. License contracts should be reduced to writing. License by oral arrangement, or by implication from circumstances, is as binding on the parties as if reduced to writing, the difference lying in difficulty of proof.

Relations of employer and employee, when the latter makes an invention. Unless by express contract, or by implication from circumstances, the employee agrees that his patentable inventions should be the property of the employer, the employer has no title or claim to the invention or to the patent for it. Even if the employee has developed his invention in the time and with materials belonging to the employer, the claim of the employer is only for the value of time and materials and does not extend to the invention. Should the employer, with the employee's consent, express or implied, put the invention into use, license under the patent to continue use to the extent initiated is implied, but no such implication extends to any enlargement of the use. Many employers require or attempt to secure from their employees an express agreement that inventions shall belong to the employer, and a prospective employee should carefully read and understand any such agreement before signing.

Infringements of Patent. As the grant purports to give the exclusive right to make, sell, or use, so an unlicensed manufacture, sale, or use of the thing patented is an infringement, and the maker, seller, or user may be sued in a District Court of the United States. Suit must be brought in the district wherein the defendant resides, or where the defendant, though not residing, has a regularly established place of business, and has committed the act of infringement. In all but very exceptional cases, the courts will not grant preliminary injunctions in a suit on a patent which has not previously been held valid in another contested litigation.

Reissues of Patent. If, through inadvertence, accident, or mistake the original patent was defective, or claimed too much or too little, the error may be repaired by surrender of the patent and reissue, provided the reissue be for the same invention as was disclosed as such by the original and be applied for without unreasonable delay. The term of a reissued patent expires on the day when the original patent would have expired.

Marking Patented Articles. Unless the patentee has given particular notice of his patent, or general notice by marking the patented articles "*Patent*" followed by the number of his patent, he may not recover damages for infringement. For a patent issued prior to April 1, 1927, the notice "Patented" followed by the date of the patent is sufficient. If the patented articles themselves cannot be marked, the mark may be affixed to the packages in which they are contained. Marking requirements do not apply to process patents or to patents under which the patentee has not manufactured.

False Marking. Any person who, with intent to deceive the public, falsely marks an article or parcel with a patentee's mark, without leave or

evaporating temperature and 100 F condensing temperature. The figures are from Lloyd's Register, 1934.

Ship nationality	No. of ships	Total cubic of all ships	Average cubic per ship	Total U.S. tons of all machines	Average cubic per ton for all ships
U.S.A.	732	117,008,578	160,000	61,200	1,915
English	29	10,709,488	370,000	4,990	2,150
English	25	8,006,305	320,000	3,280	2,440
English	20	6,087,366	305,000	2,370	2,570
English	3	1,714,194	570,000	675	2,540

By far the greater number of these ships employed CO_2 as the refrigerant and brine as the distributing medium. The greater portion of the cooling work was taken up by exposed brine-pipe coils distributed over the insulated ceilings, sides, and bulkheads with hatch coils in the hatchways. Some compartments are fitted with forced air circulation for fruit carriage, but this would be a small percentage of the whole on general-purpose vessels. Purely fruit vessels, as those operating in the banana trades, would be cooled completely by air circulation over brine-pipe cooling coils arranged in batteries in the cooler casings.

In the case of ships loading nonprecooled cargoes such as fruit, these figures cannot be used. Such a vessel should have not over 1,000 cu ft cargo space per U.S. ton of machine capacity. In the case of a banana ship, about 20 percent higher machine capacity would be desirable, because the cooling-down time for the fruit from field temperature of 90 F to a delivery air temperature of 53 F should not exceed 24 hr. Allowance must be made for the large amount of heat given off by the fruit during the period of cooling down. Air temperatures lower than 53 F cannot be safely used, and *compartment temperatures should be reduced to 55 F as rapidly as possible* and in not more than 27 hr. The fans should operate at their greatest air capacity all during the cooling-down period, which includes the full loading period.

Cubic Capacity Required for Cargo Stowage. The cubic capacity of refrigerated space required for each long ton (2,240 lb) of cargo carried will differ for each type of cargo. It may be averaged with fair accuracy as follows:

	Cu Ft per Ton
Beef frozen, in quarters, not boned or pressed, and stacked in bulk with necessary dunnage	100
Beef chilled, in quarters, suspended in deck heights of not over 7 ft 0 in. clear	125
Beef boned and compressed with ½-in. strips between layers	54–70
Mutton frozen and stacked	90
Bananas stacked 2 high and 1 flat and allowing for the space of the necessary fruit bin boards	125–140
Oranges in boxes	110–120
Apples in boxes	110–120
Apples in barrels	120–125

authority, or so marks an unpatented article or parcel with patent marks, is liable to a fine of $100 for each offense, one-half to the use of the United States, and one-half to the person bringing the information to a District Court by proper action.

Proceedings in the U.S. Patent Office. Each application for patent found to be correct in form is examined in its turn. Rejections of claim or requirements of amendment must be answered by the applicant (or his attorney) within six months after the date of the official communication, or the application will be held to be abandoned. It can be renewed only by filing a fresh application, except in extraordinary circumstances.

After allowance of an application, the applicant has 6 months in which to pay the final fee. Lapse of 6 months without payment of the fee makes forfeiture of the application.

Interferences. When an application for patent is found to interfere with, *i.e.*, to present or claim substantially the same inventions as (1) another pending application, (2) a patent issued on a date less than one year prior to the date of the application in question, (3) a reissued patent, of which the original was granted on a date less than one year prior to the date of the application in question, the two interfering cases are impleaded in an action called an interference, the purpose of which is to determine, in the Patent Office, which of two or more rival claimants is the first inventor. The practice before the Patent Office in Interference is of such a character that an interference should be conducted only by legal counsel equipped with special experience in that practice.

Design Patents. The inventor of a new, original, and ornamental design for an article of manufacture may obtain a patent for such design. Design patents are granted for 3½ years (fee $10), 7 years (fee $15), or 14 years (fee $30). In other respects, the requirements for design patents are substantially similar to those for mechanical patents. Design patents protect only the ornamental design of an article, *i.e.*, its shape or ornamentation, as distinguished from its mechanical construction or its functional or utilitarian attributes.

Foreign Countries

International Convention for the Protection of Industrial Property. The important provision of the Convention is that any person who has duly applied for a patent in one of the contracting states shall have a right of priority for 12 months in making application in the other states. Such subsequent application is unaffected by any acts accomplished in the interval, as, for example, by publication of the invention or by the working of it.

The laws and regulations in foreign countries differ so much with respect to their requirements as to novelty and patentability, the effect of a public disclosure of the invention either in the country in question or elsewhere, who may obtain a patent, the term of the patent, the cost of a patent, working of the patent, taxes, importation, compulsory licenses, revocation, and other particulars that it is not practicable to make a useful summary in the space allotted to this note. An inventor interested in foreign protection should consult a patent attorney.

LUBRICATION

BY

RAYMOND HASKELL

The **maintenance of an oil film** between two sliding surfaces depends on the **viscosity** of the lubricant, the **pressure** per unit of area, the **speed** of rubbing, the mechanical **construction** of lubricated surface, and the conditions of **operation**. The last two considerations may be so varying as to make all formulas of doubtful value. The smoothness of surfaces, closeness of fit, ratio of clearance to diameter, oil grooving, and vibration may be as important in determining the proper oil viscosity to use as the load, speed, and general bearing dimensions. Truer and smoother surfaces allow closer clearances to be used and, hence, greater loads per unit area to be carried under the same conditions. It must be remembered that the temperature of oil film also will increase under these conditions, and the heavier loads and increased temperatures may cause distortion unless design takes this into account.

The increased **temperature** also may so reduce the operating viscosity of the oil as to bring the operation in the scope of boundary lubrication, *i.e.*, lubrication where the physical and chemical properties of the lubricant in relation to the bearing material become an important factor. If there is strong adhesion of the lubricant (**oiliness**) to the bearing surface (**wetting**), the resistance to removal may be great enough to prevent seizure or scoring, even though beyond the region of fluid film lubrication. If there is an actual mild chemical reaction between the lubricant and the surface, sufficient to form a thin but tough protecting film at high pressures, the lubricant is said to have extreme pressure characteristics. Both oiliness and extreme pressure properties (**film strength**) are functions not only of the lubricant, but also of the bearing material, temperature, and pressure. The coefficients of friction under oiliness or extreme pressure conditions are much higher than found where complete fluid film exists. The foregoing must not be confused with differences in load-carrying capacity depending on the character or structure of the bearing material—babbitt, bronze, brass, lead, silver, etc.—where oiliness or extreme pressure properties are not present in the oil. Some combinations of metals allow much higher load-carrying capacities than others with the same lubricant.

Lubrication of Special Machinery

Steam Cylinders. The characteristics necessary in an oil that is to be used in steam cylinders depend on the temperature and velocity of the steam and its percentage of moisture or degree of superheat. There must also be considered the type of engine, the system of oiling, the priming and foaming of the boiler, and whether the condensed steam is to be re-used or not.

High steam pressures mean high temperatures; high temperatures necessitate the use of a heavier bodied oil or a larger quantity of a lighter bodied oil, in order to maintain a film. An excess of oil is undesirable under high-temperature conditions as it may carbonize and cause gumming. It is advisable to use the heaviest bodied oil that will atomize completely under the operating conditions.

Wet Steam. Most steam is wet at some time during its passage through the engine, and even highly superheated dry steam, unless reheated, may become wet. Moisture in the steam is thrown to the cylinder walls and will displace the lubricating oil unless

MISCELLANEOUS

Lenses

Lenses are transparent bodies which, from the curvature of their surfaces, cause light waves traversing them to converge or diverge. Optical lenses have one or both surfaces of spherical curvature. Biconvex (), plano-convex (| and concavo-convex ((lenses are thicker at the center than at the edges and have a convergent effect. Biconcave)(, plano-concave)| and convexo-concave ((lenses are thinner at the center than at the edges and have a divergent effect. The distance from the center of a lens to the point at which incident plane light waves are brought to a focus is called the **focal length** (f). If u is the distance from the source of light to the lens, and v the distance from the lens at which the image is formed, then, for a biconvex lens, $1/f = 1/u + 1/v = (n-1)[(1/r_1) + (1/r_2)]$, where $r_1(r_2)$ is the radius of curvature of the lens surface nearer to (farther from) the source of light, and n is the index of refraction of the material of the lens ($=1.5$ to 2.0 for glass). For a biconcave lens, minus signs should precede the reciprocals of f, v, r_1, and r_2 in the formula. For a plano-convex or plano-concave lens, $r_2 = \infty$ and $1/r_2 = 0$. When $u = \infty$ (*i.e.*, the incident waves are plane), $f = v$; when $u = f$, $v = \infty$ (*i.e.*, the transmitted rays are parallel). The **magnifying power** of a lens is measured by $1/f$, the practical unit being that of a lens for which $f = 1$ meter. The magnifying power of a number of lenses in contact is the algebraic sum of their individual powers, the powers of diverging lenses being considered negative. Thus, for two *convex* lenses of focal lengths f_1 and f_2, $1/f = 1/f_1 + 1/f_2$; if the second lens be concave (*i.e.*, divergent), $1/f = 1/f_1 - 1/f_2$.

The **velocity of light** in a vacuum = 186,330 miles per sec. (Weinberg.)

Sizes of Type

The unit of height of a line of printer's type is the "point." 1 point = 1/72 in. Six-point type is consequently 6/72 = 1/12 in. high. The smaller sizes of type are 3½-point (Brilliant), 4-point (Excelsior), 4½-point (Diamond), 5-point (Pearl), and 5½-point (Agate). The sizes generally employed in books and periodicals are given below. The smaller sizes are not generally available.

6-point or Nonpareil	10-point or Long Primer
7-point or Minion	11-point or Small Pica
8-point or Brevier	12-point or Pica
9-point or Bourgeois	

Greek Alphabet

Alpha	Α α	Eta	Η η	Nu	Ν ν	Tau	Τ τ
Beta	Β β	Theta	Θ θ ϑ	Xi	Ξ ξ	Upsilon	Υ υ
Gamma	Γ γ	Iota	Ι ι	Omicron	Ο ο	Phi	Φ φ ϕ
Delta	Δ δ	Kappa	Κ κ	Pi	Π π	Chi	Χ χ
Epsilon	Ε ε	Lambda	Λ λ	Rho	Ρ ρ	Psi	Ψ ψ
Zeta	Ζ ζ	Mu	Μ μ	Sigma	Σ σ ς	Omega	Ω ω

the latter is compounded to resist such action. Fatty oils (lard, tallow, degras, etc.) have a stronger adhesion (oiliness) to metals than straight mineral oils and also will displace water from metal surfaces where mineral oils will not. They will also form an emulsion with the water, increasing the resistance to removal of the oil. Compounded oils (mineral oils plus fatty oils) act similarly to fatty oils and maintain oil films in presence of moisture better than straight mineral oils.

The amount of fatty oil necessary to preserve lubrication depends on the amount of water present and the nature of the mineral oil. Too much fatty oil may cause carbonization if steam is very hot, and so in superheated steam installations little or no compound is used unless the steam in the low-pressure cylinder is wet.

When condensed steam is to be used for ice making or other industrial purposes, either a pure mineral oil or one compounded with an easily removable fatty oil must be used. In some vertical marine engines, no oil is used, the walls being lubricated with condensed steam.

Recommended Properties of Lubricants for Steam Cylinders

Condition of steam	Saybolt viscosity, sec, at 210 F	Percentage of compound
Superheated steam	145–200	0–3
Saturated steam, below 150 lb per sq in	95–135	5–8
Saturated steam, above 150 lb per sq in	125–165	3–6
Very wet steam	95–135	8–10

Steam cylinder oils are generally applied by the **atomization method**, though direct application by oilers may be used on valves or other places where the steam cannot carry the oil satisfactorily. In the atomization method, oil is fed into the steam line by "spoons" a few feet back of the throttle valve. The "spoon" distributes the oil so that the steam breaks it up into a fine spray which is carried along with the steam and deposited on walls, piston rods, or other exposed surfaces. Sometimes more than one point of distribution is necessary.

The oil is fed to the spoon by a mechanical lubricator, which varies the feed according to the speed. Another type—hydrostatic—of lubricator operates by means of condensed steam displacing oil from a small supply tank into the oil feed line and to the spoon.

There is no fixed rule as to placing of spoons, except that they must be far enough away from the valve chamber to assure atomization, and not so far as to allow deposition in bends or on pipe walls.

Steam turbines demand oils of maximum stability and ability to separate quickly from water, even after long use. Turbines operate with a continuous oiling system in which the oil is regularly cleansed or filtered to remove water, impurities, or deteriorated oil. The deterioration is usually oxidation, owing to the hot oil being churned in the presence of air. Therefore, the best turbine oils are the least susceptible to oxygen.

As deterioration of oil depends on the temperature and presence of air and water, sufficient quantity of oil should be maintained in the oiling system to permit of a low average temperature, and also time for water and air to separate from the oil. If not possible to allow oil to "rest," coolers should be used, and the oil should be cleansed frequently.

When turbines alone are lubricated, viscosities between 140 and 300 SU at 100 F are used. If gears are lubricated from the same system, viscosities up to 500 SU at 100 F are employed.

Internal-combustion Engines. The larger internal-combustion engines are generally lubricated by two or three oils—one for cylinders, one for bearings, and, in case of the air injection or the two-cycle scavenging type, one oil

A.S.M.E. POWER TEST CODES

The A.S.M.E. has standardized the methods for testing the equipment ordinarily used in power plants. The Individual Test Codes include a code on General Instructions which applies to all individual tests and a code entitled Definitions and Values which states the units to be employed in reporting tests. There is also an extensive auxiliary section dealing with *instruments and apparatus* and *containing a description and analysis of* instruments commercially or otherwise available which may be used in tests of power plants and which covers instruments used for the measurement of pressure, temperature, head, quantities of material, electrical measurements, mechanical power, indicated horsepower, heat of combustion, chemical composition of fuels, oil, and products of combustion, quality of steam, time, speed, and other measurements.

The individual Test Codes include Displacement Compressors, Vacuum Pumps and Blowers, applying to rotary types of machines operated on a positive displacement principle; Centrifugal Compressors, Exhausters, and Fans; Atmospheric Water-cooling Equipment, applying only to equipment used for cooling the comparatively large amounts of water required for power or industrial purposes; Feed-water Heaters, applying to both open and closed boiler feed-water heaters; Steam-condensing Apparatus, including rules for determining the absolute pressure at the steam-inlet nozzle, the thermal transmittance of surface condensers, the amount of undercooling of the condensate, and the percentage of dissolved oxygen in the condensate; Reciprocating Steam Engines; Reciprocating Steam-driven Displacement Pumps, including both pump and engine; Stationary Steam-generating Units, including superheater, economizer, air heater, furnace, and fuel-burning equipment; Hydraulic Prime Movers; Internal-combustion Engines; Gas Producers, intended primarily for producers whose gas is to be used for power purposes; Steam Locomotives, covering laboratory and road tests; Refrigerating Systems, including reciprocating compression systems and absorption machines; Solid Fuels and Liquid Fuels, giving standard methods for the determination of those properties which indicate the value of the fuels when used in the generation of heat and power.

These Test Codes may be purchased from the A.S.M.E., 29 West 39th Street, New York City.

for the air compressors. In the small engines and especially in high-speed types, one oil suffices, though the oil may be different for different climatic conditions. When an oil is used for cylinders or air compressors, chemical stability is perhaps the most important characteristic; viscosity at the highest operating temperature is perhaps the next, though this value is becoming of less importance as greater precision of manufacture and smoother surfaces are obtained. The smoother the surface and the smaller the clearance, the lower the viscosity necessary, provided the temperature is not simultaneously greatly increased.

As speeds and powers are increased, more heat must pass into or through the lubricating oil from the piston. Heat conducted or radiated from the burning gases also tends to oxidize or polymerize the oil on the cylinder walls. The oil, therefore, must be refined or treated to withstand chemical changes and to prevent the formation of tars, varnishes, or lacquers which cause rings and valves to stick and also collect road dust and soot from the combustion chamber to form a sludge or hard carbon coating.

In a precisely made engine, oil consumption is low, but if rings get worn or stuck, not only do combustion gases "blow-by" and accelerate sludging, but also oil is pumped up into the combustion space faster than it can burn, forming carbon and fouling sparkplugs. This naturally increases oil consumption, and means a loss in power due to poor compression. New engines of the high speed automotive type, when operated at maximum efficiency of fuel, consume about one gal of lubricating oil to 150 to 200 gal of gasoline. Large buses are less efficient on account of stops and starts.

The crankshaft bearings of almost all internal-combustion engines are lubricated by a pressure circulating system. In some cases, the oil is carried even to the wrist pin by pressure, but most wrist pins are lubricated by spray from the crankshaft or excess oil from the cylinder walls. In some small engines, lubrication is almost entirely by splash from the crankshaft.

In some small two-cycle engines, as used in marine service, the lubricating oil is mixed with the fuels and feeds directly to the cylinder walls where the gasoline evaporates from it into the combustion space. Much larger quantities of oil are necessary under these circumstances. This same system, only using smaller quantities of oil, is sometimes employed for running in new engines, or even as a supposed safeguard in addition to the regular lubricating system.

Oil and bearing temperatures have risen rapidly as engine powers have been increased, to such extent that new bearing materials have become necessary. Some of these new bearing metals are very sensitive to the chemical action of oxidized lubricating oil at high temperatures and, hence, have introduced a new problem to oil producers, as well as bearing manufacturers. Such improvements have been made that bearings are now successfully carrying pressures several times as high as a few years ago, at much higher temperatures, and with thinner oil films.

Diesel-engine lubrication is little different from that of Otto cycle engines, except as to the cylinder walls. Lubrication here is complicated by the fact that although there is always an excess of air, nevertheless, in spite of this excess, complete combustion is rarely existent if operation is carried on in the most efficient manner. This results in considerable quantities of combustion-chamber soot being carried down into the lubricating oil. The successful oil must not allow this soot to coagulate or be held as a tarry mass which may cause sticking rings, valves, or even piston drag. This may

MUSCULAR ENERGY OF MEN AND ANIMALS

The accompanying table gives results obtained by Poncelet, Morin Rankine, and others. The work of Dr. F. W. Taylor shows that a maximum amount of shoveling may be accomplished by the use of a shovel taking up a load of 22 lb. Also that by the introduction of rest periods at stated intervals (determined from a study of the particular task) the amount of work done in a day by a laborer may be greatly increased above the figures given.

Nature of work	Weight moved or resistance overcome, lb w	Velocity of movement, ft per sec v	Work done per sec, ft-lb	Time of working, hr per day	Work done per day, ft-lb
RAISING WEIGHTS					
Man raising his own weight up a stair or ladder........	143	0.5	71.5	8	2,059,200
Man hoisting weight with rope and pulley, and lowering unloaded rope.........	40	0.66	26.4	6	570,240
Lifting weights by hand.....	44	0.56	24.6	6	531,360
Carrying weights on the back upstairs or a ladder, returning unloaded*............	143	0.13	18.6	6	401,760
Pushing loaded wheelbarrow up a 1:12 incline, returning unloaded................	132	0.065	8.6	10	309,600
Shoveling up earth: lift, 5 ft 8 in.....................	6	1.3	7.8	10	280,800
OPERATING MACHINES AND TOOLS					
Pushing or pulling horizontally and continuously (capstan or oar)...........	26.4	2.0	52.8	8	1,520,640
Pushing and pulling alternately in a vertical direction (pump)..................	13.2	2.5	33	10	1,188,000
Turning a crank.............	17.6	2.5	44	8	1,267,200
Horse† operating a horse gin, walking..................	99	3.0	297	8	8,553,600
Horse operating a horse gin, trotting..................	66	6.6	436	4½	7,063,200

* Dr. Taylor ("Principles of Scientific Management," p. 60) cites the instance of a laborer lifting and carrying 1,156 pigs of iron (each weighing 92 lb) up an incline into a car during a 10-hr day. Average distance of travel, 36 ft; total lift (probably not less than) 8 ft. Ft-lb of work (lifting) = 8 × 1156 × 92 = 850,816. Prior to a study of the task and the introduction of proper rest periods, the best day's accomplishment was the transporting of 305 pigs.

† Ox: w = 132, v = 2; mule: w = 66, v = 3; ass: w = 31, v = 2.6.

require a special type of oil or a special treatment, but, in any case, frequent drains are most desirable.

Airplane engines—especially those which are air-cooled—are subject to greater variations in temperature than automotive engines and, hence, have greater machine clearances. The maximum mean effective pressures and maximum temperatures are also quite high and consequently maximum stability is required in the lubricating oil. Usually a viscosity between 100 and 140 sec SU at 210 F is required. In Canada in winter, much lower values are found necessary on account of starting difficulties. Compounded oils are used, especially in Europe, but care must be taken that they do not break down to acid materials injurious to hard bearings. Some airplane engines are equipped with a combination oil heater and cooler so that oil inlet temperature can be kept constant. In order to expedite the warming up of oil in starting, a smaller quantity may be recirculated until the engine reaches desired temperature. Airplane engines work on the "dry-sump" principle. In this, there are two pumps: one pumps the oil out of the crankcase, the other pumps oil from the tank to the lubricating system.

Compressed-air Machinery. The cardinal point in the lubrication of compressed-air machinery is to supply only sufficient oil to keep the walls covered with a thin film. Trouble is usually caused by using too much oil rather than too little. The temperatures reached in air compressors are high, and an oil film subjected to these temperatures will gradually evaporate or decompose, in the latter case leaving a gummy mass which collects around valves and dead passages and may form a hard deposit with the dust from the entering air. It is advisable to use an oil with low distillation end temperature and not generally advisable to use blends of cylinder stocks. There are cases where there is excessive moisture, then it is necessary to use an oil that is compounded so as to produce an emulsion similar to that used in steam cylinders.

The Compressed Air Society suggests, as a minimum quantity of air-cylinder lubricant to maintain a film, about 1 drop of oil per minute for each 600 sq ft of cylinder wall swept by the piston per minute. This requires 1 drop per min in an 8 by 8, 6 drops in a 24 by 24, and 12 drops in a 42 by 42 in. compressor.

Refrigerating Machinery. An oil for use in refrigerating machinery should have a pour test sufficiently low to prevent its congealing on the coldest parts of the system, as some of it is unavoidably carried through to the evaporator coils. Pure mineral oils operate more satisfactorily than compounded oils, as the latter may separate or solidify under the low-temperature conditions. Compressors for ammonia and carbon dioxide are usually lubricated by applying the oil to the piston rod by means of an arrangement around the rod called an oil lantern. The function of this is not only to supply oil to the cylinder, but also to prevent gas from escaping and air from entering the cylinder. In the wet ammonia process, mineral oil clings well to the cylinder walls as the liquid dissolves in the oil, forming a sort of emulsion. In the dry-ammonia and carbon dioxide processes, the adhesion to the walls is not quite so good, and it may be necessary to use auxiliary oilers to get complete lubrication.

In case of machines using various refrigerants such as sulphur dioxide, methyl and ethyl chloride, and Freon, which in liquid state are soluble in oil; a light-bodied straight mineral oil is still satisfactory, as when acting as a lubricant it is in contact with the refrigerant when it is in a gaseous state. In

According to D. K. Clark, a laborer can exert 0.1 hp for 8 hr a day on a windlass or pump, and for periods of a few minutes as much as 0.5 hp. The maximum force which a man can exert in pushing or pulling is 110 to 130 lb; the greatest weight he can ordinarily carry is about 330 lb; the weight he is capable of sustaining ranges from 450 to 650 lb.

Performance in Transporting Loads Horizontally

(The quantity wv is not the work done)

Nature of transportation	Weight moved, lb w	Effective velocity,* ft per sec v	Transport per sec, ft-lb wv	Time of working, hr per day
Man walking unloaded	143	5.0	715	10
Man wheeling load w in a wheel barrow, returning unloaded	132	1.7	224	10
Man traveling with load w on back	88	2.5	220	7
Man carrying load w on back, returning unloaded	143	1.7	243	6
Horse drawing cart, loaded with w, walking	1,540	3.6	5,544	10
Horse drawing cart loaded with w, trotting	770	7.2	5,544	4½
Horse walking with loaded cart, returning empty	1,540	2.0	3,080	10
Horse carrying burden w, walking	264	3.6	950	10
Horse carrying burden w, trotting	176	7.2	1,267	7

* Distance through which w is transported ÷ total time including unloaded return, if any.

The draft of horses is reduced by working them in teams. The draft of a horse in a 2- (4-) [8-] horse team is but 98 (80) [49] percent of that exerted by the horse when worked alone. A 1:100 grade reduces the draft 10 percent; a 1:50 grade, 20 percent; a 1:30 grade, 35 per cent; a 1:20 grade, 60 percent, and a 1:10 grade, 75 percent.

this state, the solubility in oil is not sufficient to harm the lubricating ability of the oil. As the solubility depends on pressure, the gas alternately enters and leaves the oil with pressure changes. A satisfactory oil must allow this gas to come out without foaming. To prevent chemical change under operating conditions the system should be free from moisture and the oils dehydrated.

Refrigerating machinery should in all cases contain an oil separator, as it is impossible to prevent oil being carried out of compressors with the gas. The oil so collected can be re-used; it is sometimes purified before returning to the system.

Textile Machinery. In the textile industry, spindle oil and stainless oil are employed. Spindle oil is highly refined, free from gumming properties, and designed to prevent rusting. For light spindles an oil of about 50 to 60 sec, for heavy spindles 90 to 100 sec SU at 100 F should be used. Stainless oils are usually highly refined petroleum products combined with neatsfoot or other fixed oils. The object is to have an oil that will not show spots on the fabric and that can be easily removed by washing. This latter characteristic is especially essential where the fabric must be dyed or printed after it is formed.

Gears, especially those operating under heavy loads, should use a viscous lubricant that will not be easily displaced from the teeth by squeezing or rubbing, or thrown off by centrifugal force, and will not flow appreciably under ordinary temperatures. With steel mill roll pinions, this compound should have incorporated with it some product that will increase its adhesiveness and prevent its being washed away by water, even under pressure. In places such as cement mills where there is considerable dust flying, heavy oil and frequent feed may be required so as to wash off the accumulated dirt. If gears run in a bath, a heavy oil can be used.

Some modern gears are designed to operate continuously with heavier loads than can be safely carried by straight mineral oils. These gears require an extreme pressure type of lubricant, especially if there is any "shock" loading. These lubricants contain a chemical that reacts with the metal under the instantaneous pressure and temperature conditions so as to prevent welding of metal parts under the very extreme loads where mineral oils would be wiped off. The most active types of extreme pressure lubricants cannot be used under continuous heavy loading, as corrosion is apt to take place. A proper lubricant should only be active at the instant of extraordinary pressure or demand, which should be of short duration.

Chains, if heavy, should be lubricated similarly to ordinary gears. If light and enclosed in a bath, an oil of 300 to 500 sec Saybolt at 100 F should be used; if not enclosed, a viscosity of 150 to 200 sec at 210 F will usually avoid loss by throwing off due to centrifugal force.

Wire ropes should be treated hot with a heavy viscous straight mineral product that will penetrate the strands when hot, but not drop from the rope when at working temperatures. Lubricants must also be applied to the outside occasionally.

Lubricating Systems. Most circulating systems are pressure fed, i.e., the oil is forced from a pump directly to the bearings or gears. The pump may be directly connected or geared to the main shaft or may be driven by a separate motor. The advantage of the former is that the quantity of the oil fed depends on the speed of the engine and is positive. The advantage of the latter is that the oil can be circulated before the machine is started.

All systems have **cooling** and **filtering** or **cleansing** units. The cooling tank is similar to a steam condenser and is generally installed before the cleanser. In some plants, the oil is first passed through a heating tank where it is heated to expedite the separation of air and water. After settling, the oil may be cleansed by passing through filter cloths or by means of **centrifuges**. Some systems pass all the oil through the cleaning apparatus on each cycle, but it is common practice either to clean the oil intermittently or to by-pass a small percentage of the whole continuously through the filters or centrifuges.

In small units, the oil is generally cooled and allowed to settle and not filtered. There should be sufficient capacity in settling and supply tanks so that the oil comes to

CONTENTS

rest on each cycle and is used only a few times a day. Two entirely different lots of oil are often used—one remains at rest, while the other is being used.

All strainers should be installed in duplicate to provide for cleaning and should have a by-pass with relief valve so that if the strainers become clogged the supply of oil will continue. The water pressure in coolers should be less than the oil pressure, to prevent leakage of water into the oil. Some systems pump continuously from the sump or settling tanks to the supply tank in excess of the quantity of oil used, allowing the excess to overflow. Other systems pump only when the oil level in the supply tank gets low and stop automatically when the latter is full. The latter have the advantage of allowing the oil to remain quiet in the supply tank and give better opportunity for the settling out of water and impurities. Sometimes the lubricating pump runs slowly at all times and speeds up when the oil reaches the low level.

Specifications. The most generally used specifications at the present time are those formulated by the United States Navy. These, with their general usage, are given below. In addition to the specifications listed, the Navy Department demands that the oil pass a "work-factor" test. The oil is given a rating by this test according to the change in certain particular physical characteristics after a "run" in a particular type of bearing under

United States Navy Requirements for Lubricating Oils

TESTS AND TRIALS OF MACHINERY

BY

D. C. MacMILLAN

TESTS PRIOR TO INSTALLATION

The American Bureau of Shipping and *the Marine Inspection Service of* the U.S. Coast Guard require that certain parts of machinery and piping be tested during manufacture or erection. The tests to be performed at the equipment manufacturer's plant or at the shipyard prior to installation (but not including material tests) are briefly described below:

Steam Engines. The following hydrostatic tests are to be witnessed by the American Bureau of Shipping surveyors:

1. High-pressure cylinder, liner, and valve chest to one and one-half times the boiler pressure.

2. Low-pressure and intermediate-pressure cylinders, receivers, and valve chests to one and one-half times the pressure of their relief valves, with a minimum of 30 psi.

Steam Turbines. The following tests are to be witnessed by the American Bureau of Shipping surveyors for all turbines over 135 shp:

1. Turbine casings are to be subjected to hydrostatic tests of one and one-half times the working pressure. For this purpose the casings may be suitably divided by temporary diaphragms for the proper distribution of the test pressures.

2. The turbine is to be tested to 15 percent above the maximum designed speed to operate the overspeed governor.

Diesels. The following hydrostatic tests are to be witnessed by the American Bureau of Shipping surveyor except as noted:

1. All relief valves are to be tested and set in the presence of the surveyor.

2. Cylinders and liners are to be tested to one-half the initial pressure. Where cylinders or liners are so designed that the parts subject to internal pressure may be accurately gaged for thickness of materials, the hydrostatic pressure may be reduced to 50 psi.

3. Water jackets are to be subjected to a pressure of 50 psi.

4. Air-compressor cylinders are to be subjected to a pressure equal to one and one-half times the maximum pressure.

5. Air-cooler coils are to be subjected to a pressure equal to one and one-half times the maximum pressure.

Tests of items under paragraphs (4) and (5) are to be made at the manufacturer's plant but need not be witnessed by the surveyor.

Condensers. The American Bureau of Shipping surveyor shall witness a hydrostatic test of the condenser body, with tubes and ferrules fitted, to 15 psi. (Also see Pressure Containers, p. 1915.)

Pumps. There are no requirements for tests prior to installation. However, it is general practice to test the steam ends of reciprocating pumps hydrostatically to one and one-half times the working pressure and the water ends to twice the working pressure. Centrifugal pump casings are generally tested to one and one-half times the shutoff pressure.

specified conditions. The less the oil changes under this test, the better the rating in its class.

Viscosities of lubricants are usually determined by the Saybolt Universal viscosimeter (see p. 244) although the Engler viscosimeter is also used. With this instrument, the outflow time in seconds for 200 cc of the oil is observed; when divided by the outflow time for 200 cc of water at 68 F, it gives results in Engler degrees. The outflow time of the water must be between 50 and 52 sec; the usual time for an instrument of normal dimensions is 51.3 sec. The **Redwood Standard** viscosimeter is the usual instrument in Great Britain; a modification of it, the **Redwood Admiralty** viscosimeter, is used in testing oil supplied to the British Navy.

There is a strong tendency at the present time to use **kinematic viscosity** expressed in **centistokes.** An approximate conversion table showing the relationship among the various viscosity units as developed by the Standard Oil Development Co. is given below. The values for the Saybolt and Redwood instruments vary slightly with the temperature of operation. The supplementary table indicates the magnitude of this variation.

Kinematic Viscosity Conversion Table
Centistokes to Engler, Saybolt, and Redwood Units

Centistokes	Engler degrees	Saybolt seconds at 130 F	Redwood seconds at 140 F	Centistokes	Engler degrees	Saybolt seconds at 130 F	Redwood seconds at 140 F	Centistokes	Engler degrees	Saybolt seconds at 130 F	Redwood seconds at 140 F

Piping. Tests (material and hydrostatic) on all plain piping to be used for pressures over 150 psi are required by the American Bureau of Shipping at the manufacturer's plant. The surveyor shall witness the following tests on fabricated piping after bending and attachment of flanges:

Steam, boiler-feed, and blow-off pipes, valves, and fittings to twice the working pressure, but not more than the working pressure plus 1,000. For fusion-welded piping, see below.

The U.S. Coast Guard Marine Inspection Service requires that sections of main and auxiliary steam piping subject to boiler pressure, also feed piping, shall be tested hydrostatically with flanges attached to a test pressure equal to twice the maximum allowable working pressure of the boiler. This test is to be witnessed and certified by the inspector.

The Marine Engineering Regulations (August, 1943) of the U.S. Coast Guard also require that all welded Class I piping (piping for pressure over 125 psi gage, hot-water piping for temperatures over 200 F, and oil piping for temperatures exceeding 150 F regardless of pressure) be tested after fabrication to twice the maximum pressure to which the piping will be subjected in service.

Air Compressors. No tests required other than for compressors used with diesels, as noted above.

Boilers and Other Pressure Containers. Items included to be tested by the American Bureau of Shipping:

1. All boilers intended for working pressure above 30 psi.
2. All unfired pressure containers intended for working pressures above 100 psi.
3. Unfired pressure containers intended for working pressures of 100 psi and less whose shell diameters are more than 30 in. and which are necessary for the safe operation of the vessel, such as condensers, evaporators, feedwater heaters, coolers, and other similar pressure containers.

The American Bureau of Shipping surveyors are to witness hydrostatic tests on the above to a test pressure not less than one and one-half times the working pressure for containers of plate or pipe construction and twice the working pressure for cast shells. In no case shall the test pressure be less than 15 psi.

Requirements of the U.S. Coast Guard, Marine Engineering Regulations concerning boilers are quite detailed. Regarding evaporators, heaters, traps, separators, pressure vessels, and miscellaneous appliances, they require that shells made of plate construction be subjected to a hydrostatic test equal to one and one-half times the working pressure for which it is designed; that coils and all cast shells shall be tested to twice their respective working pressures; and that these tests be witnessed by an authorized inspector.

Fusion-welded Boilers and Other Pressure Containers. The American Bureau of Shipping requires that all fusion-welded boiler drums and other pressure containers, also fusion-welded piping, shall be subjected to a hydrostatic test pressure of one and one-half times the allowable working pressure and, while under this pressure, shall be given a thorough hammer or impact test. The hammer test shall consist of striking the plate at about 6-in. intervals on both sides and for the full length of the welded joints. The weight of the hammer shall be approximately 1 lb for each $\frac{1}{16}$ in. of the plate thickness but not to exceed 10 lb. The edges of the hammer should be rounded to prevent defacing the plates.

PATENTS FOR INVENTIONS

BY

ODIN ROBERTS

(Revised by Robert Cushman)

REFERENCES: Albert H. Walker, "Patents," Baker Voorhis & Co. William C. Robinson, "Patents," Little, Brown.

United States of America

What Subject-matter Is Patentable. Any original and useful art (*i.e.*, process or method), machine, article of manufacture, or composition of matter, or any improvement on either, or any asexually reproduced new variety of plant other than a tuber-propagated plant, which has not been

(1) Known to or used by others in the United States prior to the invention or origination;

(2) Described anywhere in any patent or printed publication prior to the invention or origination, or more than one year before application is made for patent in the United States;

(3) In public use or on sale in the United States more than one year before application is made for patent in the United States;

(4) Patented to the inventor in some other country, which by treaty or convention has established reciprocal relations with the United States in patent matters, upon an application filed more than 1 year prior to the patent application in the United States. (This applies to practically all civilized countries.)

Who May Apply for Patent. The original inventor, or inventors jointly, if more than one. The existence of joint invention can be determined only by the facts of each case. The only general rule is that if two or more have worked and consulted together in the development of an invention they are properly joined as applicants for patent. The *owner* of an invention, by assignment and sale from the inventor, may not *apply* for patent, but may receive the patent as assignee, provided the deed of assignment has been recorded in the Patent Office.

Term of Patent. Seventeen years from the date of issue. No extensions are granted under the general law.

The patent grant gives to the patentee for the term of the patent, the sole and exclusive right to manufacture, sell, and use the alleged invention patented.

The patent application should be prepared by a competent solicitor. For information concerning the forms and rules, obtain from the Commissioner of Patents, Washington, D.C., a copy of the Rules of Practice of the United States Patent Office.

Cost of Obtaining a Patent. The Patent Office fees are: Filing fee and final fee to obtain patent after allowance. Each fee is \$30 plus \$1 for each claim in excess of twenty. The cost of preparing drawings and specifications will, of course, vary with the subject-matter.

Sale, or assignment of patent, to be binding, must be by an instrument in writing. Acceptable forms are found in the Rules of Practice of the Patent Office. To provide for constructive notice to all, an assignment must be recorded in the Patent Office within 3 months of its date.

Following this test, the pressure shall be raised to twice the working pressure and held there for a sufficient length of time to permit a thorough inspection of all joints and connections. The U.S. Coast Guard requires a similar test.

Refrigerating Machinery. The American Bureau of Shipping requires that compressors, separators, condenser and evaporator coils, headers, connections, and all other parts subject to high pressure are to be tested by hydraulic pressure to three times the working pressure and afterward to an air pressure of one and one-half times the working pressure while submerged in water.

Gas condenser and evaporator casings are to be tested to a hydraulic pressure of not less than twice the working pressure. The tests required in this and the preceding paragraph are to be made at the plant of the manufacturer whose affidavit may be accepted by the surveyors.

Electrical Equipment. The American Bureau of Shipping requires that electrical propulsion generators and motors and auxiliary generators and motors of 100 kw and over shall be tested in the presence of and inspected by the surveyors at the plant of the manufacturer. For auxiliary machines of less than 100 kw the tests may be carried out by the manufacturer whose certificate of tests will be acceptable and should be submitted upon request from the Bureau. Sufficient tests shall be made to ensure that the generators and motors are in accordance with the requirements and, for original units of a type, shall include rated-load heat run, plot of saturation curve, regulation tests at operating temperature, cold resistance measurement, air-gap check, commutation check, end-play setting, insulation resistance, running balance, bearing temperatures, and high potential test.

For subsequent duplicate generators and motors the tests shall include plot of saturation curve, cold resistance measurement, air-gap check, commutation check, end-play setting, insulation resistance, running balance, bearing temperatures, and high potential test.

Spare rotors for propulsion apparatus and auxiliaries of 100 kw and over shall be dynamically balanced in the presence of a surveyor, and the tests shall include cold-resistance measurement, insulation-resistance and high potential tests. Spare coils shall be tested for short-circuited turns; in addition, the regular high potential test shall be applied if ground insulation is assembled on the coils.

Controls for propulsion equipment shall be inspected when finished and dielectric tests made on the various circuits. The satisfactory tripping and operation of all relays, contactors, and the various safety devices shall also be demonstrated.

Cables for the propulsion equipment shall be subjected to dielectric and insulation tests in the presence of a Bureau Surveyor. All other cables are to be tested to stated requirements by the manufacturer whose certificate of such tests may be accepted.

Detail insulation tests of generators, motors, cables, and controls are also specified.

INSTALLATION TESTS

General

Tests are required on all piping and equipment after installation in the vessel and are to be performed in the presence of the inspectors of approval agencies requiring the tests, such as the U.S. Navy, U.S. Maritime Com-

GRAPHICAL REPRESENTATION OF FUNCTIONS

For graphical methods in statistics, etc., see W. C. Brinton's "Graphical Methods for Presenting Facts."

EQUATIONS INVOLVING TWO VARIABLES

The Curve $y = f(x)$. To represent graphically any function, y, of a single variable, x, lay off the values of x as abscissae along a uniformly graduated horizontal axis, whose positive direction (as usually chosen) runs to the right, and at each point on this x-axis erect a perpendicular (called an ordinate) whose length represents the value of y at that point. The unit of measurement for the y-scale, whose positive direction (as usually chosen) runs upward, need not be the same as the unit for the x-scale. Draw a smooth curve through the extremities of the ordinates; this is the **graph** of the given function in rectangular co-ordinates, or the **curve** of the function.

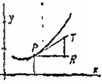

FIG. 1.

To measure graphically the rate of change of the function at any point P (Fig. 1), draw the tangent at P; then **rate of change** at $P = RT/PR$, where RT and PR are measured in units of the y-axis and x-axis, respectively. This ratio, which is positive if RT runs upward, negative if RT runs downward, is equal to the derivative of the function at the point P (see p. 157).

Graphs of Important Functions. Figs. 2–9 show the graphs (in rectangular co-ordinates) of the most important elementary functions, namely:

The **linear function,** $y = mx + b$ (Fig. 2).

The **power functions,** $y = x^n$ [n positive (parabolic type); n negative (hyperbolic type)] (Fig. 3).

The **exponential function,** $y = 10^x$ or $y = e^x$, and the **logarithmic function,** $y = \log_{10} x$ or $y = \log_e x$ (Fig. 4).

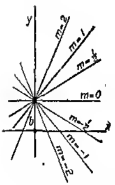
The **trigonometric functions** (Fig. 5), and the inverse trigonometric functions (Fig. 6).

The **hyperbolic functions** (Figs. 7 and 8) and the inverse hyperbolic functions (Fig. 9).

Various **special functions** (Figs. 10–12).

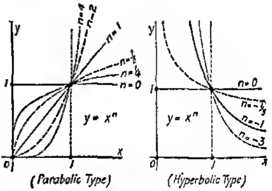
By a slight modification, each of these diagrams may be made to represent a somewhat more general function than that for which it is primarily intended. For, if x is replaced by $x - a$ in the equation, this merely requires re-numbering the x-axis so that each number is moved a units to the left; and similarly, if y is replaced by $y - b$ in the equation, this merely requires re-numbering the y-axis so that each number is moved b units downward. (Such a change is called a translation of the curve to the right, or upward.) Further, if x is replaced by x/c [or y by y/c] in the equation, it is merely necessary to multiply each of the numbers written along the x-axis [or y-axis] by c, in order to adapt the graph to the new equation. (Such a change is called a "stretching" of the curve along one of the axes.)

Empirical Curves. Any set of values of two variables x and y can be represented by plotting the points (x,y) on rectangular co-ordinate paper, and drawing a smooth curve through these points. The points which correspond to actual data should be clearly indicated by small circles or crosses, intermediate points being spoken of as interpolated points. While this process of graphically interpolating a continuous series of points *between* given values is usually fairly safe, the process of extrapolation—that is, extending the curve *beyond* the range of the given values—is dangerous.



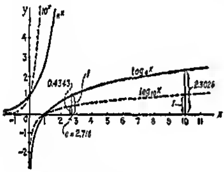
Linear function, $y = mx + b$.

Fig. 2.



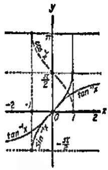
Power function, $y = x^n$.

Fig. 3.



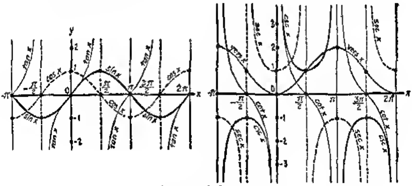
Exponential function (10^x or e^x).
Logarithmic function ($\log_{10} x$ or $\log_e x$).

Fig. 4.



Inverse trigonometric functions.

Fig. 6.



Trigonometric functions.

Fig. 5.

To Find a Mathematical Equation to Fit a Given Empirical Curve. This problem is one which in general requires much patience and ingenuity. Only the simplest cases can be mentioned here.

Case 1. If the given empirical curve is a straight line, then the law connecting the given values of x and y is $y = mx + b$, where m = the slope of the line, and b = the value of y at the point where the line crosses the y-axis. If

mission, U.S. Coast Guard Marine Inspection Service, and the American Bureau of Shipping. These tests will determine the success of the installation and are to be performed prior to the dock trials, except such tests as cannot be adequately made at the dock owing to local conditions may be performed at sea. Given below are installation test procedures for vessels built to these requirements.

Data sheets, giving the name of the vessel, hull numbers, date of test, observed data, name plate data, and space for the inspectors initials should be prepared for each item of equipment.

Preliminary Installation Tests

All piping systems should be carefully examined and tested before the official hydrostatic test is applied. The system should be examined to see that it conforms with the approved arrangement and diagrammatic plans, with attention paid to all small lines, pressure gages, thermometers, pressure switches, etc. Particular attention should be paid to see that check and stop-check valves are not installed backward in the lines. A preliminary hydrostatic test should be conducted on each system, and all leaks should be made tight.

Megger or equivalent tests should be made on each electric cable during the installation at the time connections are being made. These tests should be conducted in accordance with the procedure for insulation-resistance tests.

Before conducting any test, the shipyard operator should familiarize himself with the equipment and with all operating instructions furnished with it.

All engine-room and deck auxiliaries should be tested by the shipyard prior to the official tests. These tests may be conducted using a shore supply of current for the motors or steam for the steam-driven auxiliaries. The duration of the preliminary tests should be sufficient to indicate that the machinery is functioning properly. Before an electrical test is started, all connections should be carefully checked and insulation-resistance readings should be taken.

All motors throughout the ship for nonreversing service should be checked for proper direction of rotation. When the direction of rotation is established, a careful check of the brush rigging should be made and, if necessary, reaction-type brush holders should be reversed. Adjustments of this nature should be made in strict accordance with the instructions furnished by the motor manufacturer.

The lube-oil system should be properly cleaned and flushed in an approved manner.

Piping Systems

In general, these tests are to be conducted before the application of lagging obscures proper inspection for leaks, but in special cases the contractor may, upon written application, conduct them after portions of the lagging between pipe joints have been applied.

The sequence of piping system tests may be decided by the contractor to suit conditions, but sufficient notice shall be given to the interested parties so that they may prepare for and witness the tests. In this respect the contractor shall prepare a schedule of piping system tests giving the approximate date on which he plans to conduct each test.

overload condition shall be created without causing damage to the installation. Adjustments shall be made to effect operation of the protective devices at the specified overload rating applicable. A sample data sheet is given by Fig. 1.

Steam Reciprocating Pumps. Each reciprocating pump should be brought up to its rated double strokes per minute and total head. The designed total head should be obtained by properly throttling a valve in the discharge of the pump.

Readings should be taken of all data at least every 10 min during the continuous test that should be of at least ½-hr duration.

Any unusual operating conditions should be noted and carefully described on the data sheet at the time the test is run. Erratic behavior of the pump should be carefully recorded at the time of occurrence in order that any serious defect may be detected and serious failure prevented. Particular note should be made of the amount of noise, gland leakage, correctness of alignment, length of stroke, and operation of the valve gear. The operation of the relief valve and its setting should be checked and, where a governor valve is fitted, its operation should also be checked.

Turbine-driven Pumps. The turbine-driven pumps should be operated at rated speed under service conditions. Readings should be taken of all data at least every 10 min during the continuous test that should be of at least ½-hr duration.

Any unusual operating conditions should be noted and carefully described on the data sheet at the time the test is run. Erratic behavior of the pump or turbine should be carefully recorded at the time of occurrence in order that any serious defects may be detected and serious failure prevented. Particular note should be made of the amount of vibration, noise, gland leakage, correctness of alignment, and adequacy of lubrication. When possible, an estimate of the amount of fluid pumped should be obtained.

The operation, settings, etc., of control and protective devices shall be demonstrated and checked.

Forced-draft Fans

Each forced-draft fan shall be operated for 1 hr at its maximum rated speed and pressure. The proper pressure shall be maintained by adjusting the control dampers or boiler registers. Readings shall be taken every 10 min of all data.

After completion of the above test, the fan shall be operated at the following conditions to demonstrate the characteristics over the operating range:

Registers open at normal speed.
Registers open at maximum speed.
Registers closed at normal speed.
Registers closed at maximum speed.

Any unusual operating conditions should be noted and carefully described on the data sheet at the time the test is run. Erratic behavior of the equipment should be carefully recorded at the time of occurrence in order that any serious defect may be detected and serious failure prevented. Particular note should be made of the amount of vibration, noise, and adequacy of lubrication.

If the fan is motor-driven, test requirements are the same as given above for Motor-driven Pumps, p. 1925.

Installation tests on piping systems should be conducted only after all hydrostatic shop tests have been completed as required by the U.S. Coast Guard, American Bureau of Shipping, and as noted on the piping detail drawings. If any welding is done on a pipe after it has been installed in the vessel, this pipe shall be retested as required by the U.S. Coast Guard, American Bureau of Shipping, and as noted on the piping detail drawings.

All equipment, such as heaters, coolers, or strainers in the system, which are subjected to the pressure of the system, shall be tested with the system. For equipment such as heaters or coolers pressure shall be applied to one side at a time so that adequate inspection for leaks may be made.

Label plates on valves, manifolds, etc., and drains and instruction plates on pipe hangers (where required) shall be installed in their entirety at the time of the test. If, for any reason, some of these items should be omitted, the same shall be specifically noted in the report.

The systems shall be cleaned thoroughly of all dirt, rust, scale, etc., before they are tested.

Pressure is to be applied to each system in its entirety and, in cases where this is not practical owing to tank suctions and the like, the joint nearest the tank, etc., shall be broken and blanked, so as to include as much of the system as it is possible in the test. Specific mention shall be made of those joints that have been excluded from the test so that their tightness may be observed under service conditions.

The pressure specified shall be maintained long enough to permit an adequate and detailed inspection of the system as well as to repair the leaks that occur. In the cases where it is necessary to remove the pressure to effect repairs, the test pressure shall be applied again after the leaks have been repaired.

Where piping is to be subjected to a test pressure in excess of the relief valve setting, the valves should be gagged or fitted with a blank on the inlet to the valve. An attempt should not be made to reset the relief valves to the higher test pressure.

All gages used for testing should be calibrated before conducting the test.

For a more detailed description of the Freon piping test, see procedure for testing Refrigeration Equipment, p. 1929.

Typical piping test requirements are given by Table 1.

Insulation-resistance Test

Megger or equivalent tests should be made of each cable during the installation at the time connections are being made to equipment. Circuit continuity should be checked at the same time to avoid errors. Record weather conditions, particularly humidity at the time of measurement.

A record of insulation resistance should be kept, and a tabulation should be made on the test form before the dock trials. The tabulation should then be submitted to the local maritime commission inspector for approval, on the basis of Par. 45.03 of *A.I.E.E.* 45.

The minimum insulation resistance of all generators and motors should be approximately 250,000 ohms. The minimum insulation resistance of fields of machines separately excited with voltage less than the rated voltage of the machine should be of the order of ½ to 1 megohm.

Megger tests shall include positive to negative, positive to ground, and negative to ground for power feeders. For lighting feeders, the same tests

Air Compressors

Each air compressor shall be operated at its designed speed and pressures. The compressor should be tested with all control apparatus in place and operating. It should be brought up to the rated speed and discharge pressure. Air should be bled from a convenient point in the system to permit the compressor to operate continuously for the duration of the test.

After completion of the heat-run test, the setting and operation of the unloading valves, relief valves, start-stop switch, as well as the ability of the compressor to charge the system from atmospheric pressure to the rated pressure, shall be demonstrated.

Motor test requirements are the same as given above for Motor-driven Pumps, p. 1925.

Oil Purifiers

The purifier shall be operated at its rated capacity with oil at proper temperature to demonstrate satisfactory operation and installation. The test should also demonstrate that the attached pumps are able to take suction through the normal or emergency suction and deliver the normal quantity of oil at the required pressure to the storage, settling, and sump tanks.

The motor should be brought up to its rated speed, and the discharge valve on the discharge pump should be throttled to obtain the designed discharge head. Readings should be taken every 15 min during continuous operation until the temperatures no longer show an increase. The time of continuous test shall be not less than 1 hr. Attention should also be paid to the water discharge to see if any oil is carried over with it to the sludge tank.

Any unusual operating conditions should be noted and carefully described on the data sheet at the time the test is run. Erratic behavior of equipment should be carefully recorded at the time of occurrence in order that any serious defect may be detected and serious failure prevented. Particular note should be made of the amount of vibration, noise, gland leakage, correctness of alignment, and adequacy of lubrication.

Motor test requirements are the same as given above for Motor-driven Pumps, p. 1925.

Emergency Diesel Generator

Generator tests similar to those described above for Turbogenerators (p. 1922) shall be made.

The automatic emergency diesel-engine starting mechanism and the bus transfer switch shall be tested under a simulated emergency condition. Such condition should be effected by opening the emergency switchboard breaker at the main switchboard while the main switchboard is energized.

In order to demonstrate the load characteristic of the machine, vary the generator load from no load to 125 percent load, and back to no load in 25 percent load steps. The generator field rheostat and the diesel governor should not be adjusted during this test. Particular note should be paid at this time to the engine exhaust. The engine at 125 percent load may show a light haze, but at all ratings at and below full load the exhaust should be practically clear.

The 4-hr heat-run test should not be started until the generator temperatures are fairly constant when the generator is operating under full load.

shall apply plus meggering the neutral leg to ground and between positive to neutral and negative to neutral.

Main Boilers

Boiler Hydrostatic Test. A hydrostatic test shall be conducted at one and one-half times the design boiler-drum pressure for such a period to permit a careful examination of every part of the boiler. All leaks developing during this test shall be reported together with the pressure at which they occurred and the method of correction. After completing the test, the boiler shall be opened up for inspection, and all pressure parts shall be examined.

125 Percent Steam Test. A test under steam shall be applied to the boiler and main and auxiliary steam piping at a pressure of one and one-quarter times the design pressure and a temperature approximately equal to the service temperature. For a typical case, the design boiler-drum pressure is 525 psi gage. The design (normal sustained operating) pressure of the main and auxiliary steam piping is 465 psi gage. The superheater safety-valve setting is 480 lb. The corresponding steam test pressure is 600 psi gage. Sufficient steam is to be bled from the superheater outlet by operating the turbogenerators or some other steam-driven unit, so that the normal temperature will be obtained. The duration of the test shall be of such a time as to permit an adequate inspection of the boiler and piping system, but in no case shall the test be less than 1 hr. A complete report shall be made on this test and submitted for approval. All leaks and other pertinent information shall be included in the report. For the steam test, the regular safety-valve springs should be replaced by springs designed to operate at the test pressure. After the completion of the test, the test springs should be replaced with springs designed to operate at the maximum allowable working pressure.

During the test, the tightness of the boiler furnace, uptakes, and smoke pipe shall be observed and a note made on the test report of the observed condition.

Cold-ship Emergency Starting. Cold-ship emergency starting test shall be demonstrated on at least one ship of each group of similar ships being built by each contractor. Steam shall be raised from cold boiler to normal operating conditions. A report shall be submitted stating the procedure used, the time of the various steps taken, and any difficulties encountered.

Safety-valves Setting. The valves shall be set under steam pressure in the presence of the various inspectors. The valves shall be popped by steam pressure so as to obtain the full designed lift and then permitted to reseat. Note the popping and reseating pressures and amount of simmering or chattering.

The blowdown of all valves shall not exceed 3 percent of the popping pressure.

Demonstrate the ability of the safety-valve easing gear to lift the safety valves at zero pressure.

Hydrostatic Testing of Condensers

The water sides of the main and auxiliary condensers shall be tested at the same time as the circulating-water piping to a pressure of 30 psi gage. All leaks that may occur shall be made tight under test conditions.

The data for the heat run should then be taken at ½-hr intervals. Immediately after the full-load test is completed, the equipment shall be operated at 125 percent load for 2 hr.

During the test any unusual operating conditions should be noted and carefully described on the data sheet at the time the test is run. Erratic behavior of equipment should be carefully recorded at the time of occurrence in order that any serious defect may be detected and serious failure prevented. Particular note should be made of the amount of vibration, noise, correctness of alignment, adequacy of lubrication, and cooling. Attention should also be paid to see if the generator room is properly ventilated so as not to cause any undue heating of the space.

At the conclusion of the test, measure the insulation resistance of the windings before the generator temperature can change appreciably.

The operation of the overspeed governor shall be demonstrated under the supervision of the manufacturer's representative. The main governor should be checked for its ability to return the engine to normal speed after it has been reduced or increased from that speed, and the time of such return noted.

Refrigeration Equipment

The following give the tests for a Freon-12 direct-expansion system:

Piping Test. Each system, on completion and before pipe covering is installed, should be tested as follows:

1. Charge with Freon to 10 lb. Test for leaks with halide detector.
2. Blank off bursting disk on relief valve.
3. Add bone-dry nitrogen or CO_2 to bring pressure to 315 lb. Retest for leaks. (Isolate compressor and all pressure controls and low-pressure gages.)
4. Seal system under pressure for 8 hr. Pressure drop should not exceed 5 lb if temperature remains approximately constant.
5. Release pressure to 150 lb, open compressor valves, test compressor and shaft seal for leaks.
6. Lower pressure to atmospheric pressure and replace bursting disk on relief valve.
7. Dehydrate with a portable dehydrator pump.
8. Pump lowest vacuum possible, using pumps first in parallel then in series.
9. Charge with Freon to 20 lb and retest for leaks.
10. Connect system cleaner charged with activated alumina or silica gel in the compressor suction line, using the connection provided. Circulate Freon, using compressor. Add Freon as necessary. Recharge cleaner when necessary.
11. Remove cleaner. Inspect all strainers, expansion valve, and suction regulators.

Operation Test. The refrigeration compressors shall be operated at their rated capacities. The units should be tested with all control apparatus in place and operating. Power for the motors shall be taken, using the ship's power and permanent cable installation. If winter conditions exist at the time of the test, the refrigerated compartments and surrounding spaces should be heated to not less than 70 F. All compressors should be started and brought up to speed with the entire refrigeration load connected. The com-

partments should be brought down to and maintained at the designed temperatures.

Readings should be taken on all motor data every 15 min during continuous operation until the temperatures of the motors no longer show an increase. The time of continuous test on the motors shall be not less than 1 hr. Readings of the compartment temperatures, by dial thermometers installed, and the compressor suction and discharge pressures should be taken every hour. The remaining reading should be taken every 2 hr. The time when a compressor starts and stops owing to automatic pressure control should be noted. Temperatures in all surrounding spaces shall be taken.

Any unusual operating conditions should be noted and carefully described on the data sheet at the time the test is run. Erratic behavior of equipment should be carefully recorded at the time of occurrence in order that any serious defect may be detected and serious failure prevented. Particular note should be made of the amount of vibration, noise, correctness of alignment, any extreme variations in liquid level in the receiver or oil level in the compressor, and any undue or uneven frosting of the coils or air units.

The test should demonstrate the satisfactory operation and adjustment of all thermostats, pressure switches, solenoid valves, thermal expansion valves, suction regulators, and other controls.

Insulation Test. After the compartments have been maintained at the temperatures required for a period of at least 12 hr, the machines should be shut down and the compartments kept closed for 6 hr, and the temperature rise noted. Dial thermometers should be read every 2 hr, and temporary test thermometers should be read before and after the 6-hr period. Temperature drop should not exceed 1½ to 2 deg per hr when outside temperature is 70 F or above.

Shaft-turning Gear Motor

Oil should be circulated through the turbine and gear bearings by means of the main or stand-by lube-oil service pump. All bearings should be examined to see if they have sufficient lubrication before the turning gear is started. The motor should then be started and brought up to its rated speed. Readings should be taken at least every 15 min during continuous operation until the temperatures no longer show an increase. The time of continuous test should not be less than 1 hr.

Motor test requirements are the same as given above for Motor-driven Pumps, p. 1925.

Anchor Windlass

General. The cold insulation resistance of the motor armature, motor fields, and controller wiring shall be determined before starting tests.

Centigrade thermometers of proper range shall be wedged in the motor windings and taped or otherwise secured to the bearings. Readings shall be taken before each run and at 15-min intervals during tests. Measure the hot insulation resistance at the completion of each test before the motor cools appreciably.

The motor speed shall be measured at each point of the master switch for both hoist and lower.

Record the anchor weight, size of chain, chain and rope speeds, length of chain out of pipe, brake operation, input volts, amperes, and motor rpm, and any other pertinent data.

[a] Test with boiler steam and hydrostatic test.
[b] Test with main and aux condensers.
[c] Includes 2-hr static drop test at 125 psi.
[d] Test under service conditions when conducting evap test.
[e] All welds to be hammered while under hydrostatic test.
[f] *Inner bottom piping and all other piping protected* by fuel-oil and ballast overflow.
[g] Test to maximum head obtainable.
[h] Includes all fuel-oil filling and all piping not protected by fuel-oil or ballast overflow.
[i] Test under service conditions.
[j] Test with bone-dry nitrogen or CO_2.
[k] Test with fire system.
[l] Test with heating system.
[m] Includes fire and sanitary suction piping.
[n] All steam radiators and unit heaters to be cut in.
[o] Test with safety valve test on boilers.
[p] Test all vacuum piping with air at 15 psi and apply soap solution to all joints.
[q] Test header to 1,000 psi gage static pressure drop not to exceed 300 lb in 2 min. Also plug distribution lines and test at 600 psi gage.

Approved by: ____________

No-load Windlass Test. The anchor windlass shall be operated continuously at maximum motor speed for a period of ½ hr in each direction. During this period, the bearings and gear boxes shall be inspected for heating or other indications of unsatisfactory operation.

NOTE. This test to be run before anchors and chain are attached.

Load Test at Dock. The windlass shall be operated for 15 min by hoisting and lowering each anchor. Run out as much chain as the depth of dock permits, but not over 30 fathoms.

The test described above shall be conducted once, by lowering and hoisting both anchors simultaneously.

The ability of each mechanical brake to stop and hold each anchor and chain shall be demonstrated. Let go each anchor separately, under control of brake, and catch it before reaching bottom. The operation of locking head, for satisfactory performance, shall be noted.

The ability of the solenoid brake to stop and hold the anchor and chain shall be demonstrated, while hoisting and lowering at full speed.

The ability of each warping head to produce the specified line pull at the specified speed shall be demonstrated. Note the speed, and check the pull on a dynamometer or heavy-duty crane scale, recording maximum input volts and amperes.

The ability of each warping head to develop a high light-line speed as specified shall be demonstrated. (The light-line speed shall be recorded as the average time required to haul in 50 fathoms of ship's mooring line.) Record the rpm of warping head.

Lead a line from the warping head to a heavy-duty crane scale, secure the crane-scale hook, and then heave in with the warping head until the windlass stalls. Take readings of crane scale, line voltage, and line current. Operate the master switch so that the electric brake holds the load.

Check the operation of the interlock switches on the wildcats. With the wildcats disengaged and locked out for warping service, take readings of the motor speed at each point of the master switch for both hoist and lower.

The chain stoppers for each chain shall be tested with chain in a normal riding position. Check pawl for proper seating against shoulder of chain.

Demonstrate the ability of devil's claw to hold the anchor satisfactorily in stowed position.

Capstan

The general and no-load tests are similar to those described above for the Anchor Windlass (p. 1930), and the load test is similar to the load tests of the warping head of the anchor windlass.

Cargo Winches and Booms

General. All cargo-handling equipment and rigging shall be tested after installation and shall be in strict accordance with the requirements of the U.S.M.C. Register of Cargo Gear. The tests shall be made in the presence of Maritime Commission and American Bureau of Shipping representatives, and a certificate of tests obtained.

Measure the cold insulation resistance of the motor armature, motor fields, and controller wiring before starting tests.

Centigrade thermometers of proper range shall be wedged in the motor windings and taped or otherwise secured to the bearings. Readings shall

The steam side of the condenser shall be completely filled with fresh water up to the height of the turbine flange, and air at a pressure of 15 psi gage shall be placed upon the water. The manhole and handhole plates on the water box and return heads shall be removed, and all tubes and joints shall be made tight.

Turbogenerators

For an assumed installation of two 300-kw, three-wire, 240/120-volt, d-c, shunt-wound turbogenerators, the tests should be as follows:

Before starting, the cold insulation resistance of each generator should be determined by placing one lead of a Megger or other such device on an unpainted spot on the frame and the other on each of the wires to be tested. The line switch of the generator should be open and the machine at a standstill. This will indicate the insulation resistance of the generator and leads to the switchboard. In the event that the resistance is less than 250,000 ohms, the brushes should be raised from the armature and the shunt field disconnected to determine the faulty circuit. The unit should be examined to see if it is in proper working condition.

Thermometers of proper centigrade-scale range shall be attached by putty, tape, or other suitable means to the generator bearings and stator coils. Readings shall be taken before the generator is started and at each time readings are taken during the heat run.

The generator should be started and brought up to full speed. During this period, a careful check should be made of all items to see that the turbine is functioning properly. A preliminary check of the wiring should be made by applying a suitable load on each generator. The series fields should then be checked by shorting them with a carefully placed copper bar. When each series field is shorted, the voltage should drop slightly. Any rise in voltage should be corrected by stopping the machine and reversing the improperly connected series field or fields.

The operation of the speed-control governor shall be demonstrated as follows: After the governor has been set for the desired speed, the speed shall be increased by hand operation of the governor control shaft. The governor shall then bring the speed back within the normal tolerance. By similar action, the speed shall be reduced below the set speed, and the governor shall again bring the turbine back within the tolerance.

Each generator in turn should be brought up to rated speed and the main switchboard meters calibrated. The voltage should be varied from 75 to 125 percent rated volts by adjusting the field rheostat, and readings taken of the switchboard voltmeter, and a calibrated standard voltmeter connected on the main bus. Readings should be taken at 10-volt intervals and recorded. A load should then be applied and varied between 20 and 125 percent rated current. Readings should be taken of the switchboard ammeters and a calibrated standard ammeter, having its shunt connected in series with the switchboard shunt. One standard ammeter may be used during this test if the neutral is opened.

The circuit breakers should be tested by adjusting the tripping element to 128 percent rated load on the positive and negative, and 32 percent rated load in the neutral, with dashpot disconnected. The load should be increased gradually until the circuit breaker trips. The current in each leg should be recorded at the instant of tripping. When the circuit breaker has been set

be taken before each run, and at 15-min intervals during each test. Motor voltage and current should also be recorded.

Measure the peak inrush current while moving the master switch from "stop" to the last point both lowering and hoisting for each test.

With the winch running, trip the circuit breaker or open the line switch and observe that the winch does not start when power is returned to the line until the master switch is moved through the "off" position.

Before starting any tests, the preliminary inspections, adjustments, lubrication, etc., shall have been satisfactorily completed.

Demonstrate that the topping lifts are of sufficient length to provide at least three turns of wire rope on the gypsyhead when the boom is lowered into the boom crutch.

Demonstrate that the cargo falls are long enough to lower the hook to the tank top through the last quarter of the hatch nearest the boom. At least three turns of the rope should remain on the drum, with the end of the wire rope securely fastened to it.

The ability safely to withstand the stalled-motor torque (300 percent normal current), with overload adjusted to maximum setting, shall be demonstrated on one winch for each ship, either at factory or aboard ship. The torque should be applied to both the drum and the winch head. The manufacturer shall tag those winches on which the shop test has been satisfactorily completed.

In each test, the load, motor rpm, rope speed, hook speed, input volts and amperes, and other unusual or pertinent data shall be recorded. Where the ability of the winch to handle the various specified rope speeds has not been demonstrated at the plant of manufacture, it shall be demonstrated aboard ship.

All winches shall be tested aboard ship at 100 percent of load for five complete cycles through the maximum obtainable drift.

Record the loads, speed, cycle time, time for each operation in cargo cycle, and all other pertinent data as well as any unusual conditions or occurrences.

Whatever load is specified for the normal rope load at the drum shall be raised and lowered continuously for ½ hr with a maximum speed as near 0.6 maximum possible speed as practicable. The load shall be stopped in the hold 20 sec each time to simulate service conditions. Check rheostat heating. This test is to be carried out on one winch of each type.

During the cargo winch test the adequacy of the control shall be checked and any *objectionable features noted.*

No-load Test. Operate each winch for a period of ½ hr on hoist and ½ hr on lower. Where possible, this may be done by declutching the wire-rope drums, operating the gypsies only; otherwise, it will be necessary to remove the wire rope from the drums. Take readings every 15 min, four sets minimum, record electrical temperature, rpm, motor voltage, and current. Inspect the gear boxes and bearings for heating or other unsatisfactory operation.

Load Test. The following gives a typical test for a 5-ton boom and winch:

The 5-ton booms shall be tested with a load of 14,000 lb (6.25 tons—25 percent overload), using regular tackle. Test the boom at an angle of 15 deg to the horizontal. Hoist and lower the load through full drift for five cycles, and then swing inboard and outboard as far as obstructions will permit. On one boom at each hatch, the load will be lowered into the hatch to the tank top and then hoisted out.

trip at the desired load, the dashpot may be reconnected. The grounding eaker should be tested by connecting either positive or negative bus to ound through a suitable variable resistor having capacity equal to the rating the breaker. The test should be started with all resistance in the circuit id the ground current gradually increased until the breaker trips. All quired data should be recorded.

Parallel operation of the generators should be checked at this time in rder to make adjustments of the governors or any other adjustments ecessary to the successful conduct of the succeeding tests. With the enerators running at rated speeds and with terminal voltage and line switches pen, check the polarity of the machines before attempting to parallel them or the first time. If the polarities are opposite, it will be necessary to stop ither machine and either "flash" the field or change the connections. The atter is the more laborious but, if attempted, it should be accomplished by pplying the same principles as in changing the direction of rotation of a ompound motor.

To "flash" the field, connect the shunt field by temporary wires in such a vay that the polarity will be the same in relation to the other machine when paralleled. While the one machine is at a standstill, its shunt field should e connected as just outlined, then the machine should be brought up to speed and the polarities rechecked and the line switches closed. The temporary hunt field connections can be removed either before or after the machines are paralleled.

With the generators paralleled, adjust the load to about 75 percent rated oad on each generator. Divide the load evenly at this load with rated voltage, then, without making any further adjustments of the generator field rheostat or the governor of the prime mover, decrease the load until the least loaded machine carries approximately 15 percent of rated load and take readings; then increase the load to as nearly full load as possible and take readings as required.

If the generators fail to divide the load evenly at the above three points within 15 percent of the full-load rating of each generator, it will be necessary to make adjustments to correct this condition. The first adjustments should be made on the speed of the prime movers. The data will indicate which machine required adjustment. With few exceptions, the speed adjustments will correct any unequal division of load. In the event that this is ineffective, the manufacturer of the generators must correct the windings by adding external shunts or by any other approved method.

The proper functioning of overspeed protective devices must be demonstrated. This may be done while making preliminary adjustments or while the generators are operating in parallel.

Check the behavior of the governors and regulating devices during severe operating conditions by causing intermittent load swings from 25 to 75 percent load. This should be accomplished in one switching operation or step and should be repeated several times.

The foregoing tests are advisable in order that loss of time may be avoided in the following tests. Upon completion of the preliminary tests, the generators are ready for the individual heat runs or the parallel operation test, either of which may be run first. The order will be determined by existing conditions. If all machines are warmed up by reason of the above tests, the parallel test should be made. On the other hand, if a cold start is necessary, the individual heat runs should be made.

The ability of the mechanical and the electrical brakes, on each winch, to stop and to hold a 14,000-lb load shall be demonstrated. (Hold the electric brake open when testing the mechanical brake.)

With the boom topped so as to plumb the hatch, lower a load of about 1,000 lb at full speed, to demonstrate satisfactory operation of dynamic braking (to land loads without jarring or "inching").

The ability of rig to hoist and lower a hook load to 3,360 lb at a speed of 290 fpm, using a single whip, shall be demonstrated.

The ability of rig to hoist and lower a hook load of 6,720 lb at a speed of 220 fpm, using a single whip, shall be demonstrated.

The ability of rig to hoist and lower a hook load of 11,200 lb at a speed of 112 fpm, using a two-part purchase, shall be demonstrated.

Using two winches (burtoning), the complete cargo-handling cycle shall be demonstrated, using load of 6,720 lb; noting the time for each operation as well as the total time for the cycle.

Using a load of 6,720 lb on the hook and with a single whip, the load shall be raised and lowered continuously for 30 min with a maximum speed as near 0.6 maximum possible speed as practicable. The load shall be stopped in the hold 20 sec each time. Check the rheostat heating. This test is to be carried out on each winch of each ship.

Steering Gear

General. Record the cold insulation resistance of the motor armature, motor fields, and controller wiring before starting tests.

Centigrade thermometers of proper range shall be wedged in the stator windings and taped or otherwise secured to the bearings. Readings shall be taken before each run and at suitable intervals during each test. Measure the hot insulation resistance at the completion of each test before the motor cools appreciably.

During the following tests, the feeder transfer switch shall be thrown to each position to check both steering gear feeders.

In each test, note the motor rpm, input volts and amperes, oil pressures and temperatures, and the time required to move the rudder from bardover to hardover. The oil temperature rise during each test shall be noted.

In general, the steering gear shall be examined for satisfactory performance of limit stop settings, follow-up control functioning, shift-over arrangement, valves, fittings, and packing. Any unusual conditions relative thereto shall be noted.

Dock Test. The steering gear shall be operated at the dock continuously for 2 hrs, using each motor and pump unit for 1 hr. The rudder shall be moved 30 times from hardover to hardover (70 deg in 30 sec) during the test of each unit. The time required to change from one unit to the other shall be noted. During this run the follow-up control and all rudder-angle indicators shall be tested for accuracy at the following angles: 0, 5, 10, 15, 20, 25, 30, 35 deg (port and starboard).

Note the number of turns required at trick wheel to move the rudder from hardover to hardover (70 deg) in 30 sec. Repeat the above test for the wheel located on the aft steering stand, in the wheelhouse, and on top of the wheelhouse.

Operate the steering gear from wheelhouse and wheelhouse top, using telemotor.

Operate the steering gear from wheelhouse using the gyropilot (if fitted).

The parallel operation test shall be conducted to determine the ability of all machines to parallel by operating all generators simultaneously connected to the bus.

When the 2-hr load test is completed and with all machines in parallel, vary the load from 20 percent load to full load and back to 20 percent load in approximately 20 percent load steps. Do not adjust the field rheostats during this test. Record all data required.

Speed and load regulation data should be taken with all the machines running and immediately after the parallel tests. This is accomplished by disconnecting one generator from the bus and putting a full load on the remaining generator. After taking readings, open the circuit breaker of the loaded generator and take another set of readings. No adjustments of rheostats or governors shall be made between the two readings. Each generator should be tested in this manner, recording all data.

If for any reason the bus must be energized at all times, close the circuit breaker of the idle generator at the same time the load is removed from the generator under test.

The reverse-current relay of the generator circuit breakers should be checked at this time to determine the tripping current. This may be accomplished by reversing the ammeter leads while the generator to be tested is in parallel but carrying no load; reduce the speed of the turbine until the breaker trips. Record the reverse current.

The load test or heat run for each generator is accomplished by warming up the generator until temperatures are fairly constant with rated full load. Take data as required for 4 hr at full load, then increase the load to 125 percent rated load for 2 hr. Take readings at half-hour intervals during rated-load test and at 15-min intervals during the 125 percent load tests.

During the test any unusual operating conditions should be noted and carefully described on the data sheet at the time the test is run. Erratic behavior of equipment should be carefully recorded at the time of occurrence in order that any serious defect may be detected and serious failure prevented. Particular note should be made of the amount of vibration, noise, correctness of alignment, adequacy of lubrication, operation of the turbine glands, and operation of the lube-oil coolers.

At the completion of the load tests and before the generator temperature can change appreciably, determine the insulation resistance in exactly the same manner that the cold resistance was obtained.

The operation of the overspeed trip and low-oil-pressure trip shall be demonstrated under the supervision of the manufacturer's representative. The results of the tests shall be recorded on the data sheets. The governor should be checked for its ability to return turbine speed to normal after it has been reduced or increased from that speed, and the time of such return noted.

Pumps

General. Each power-driven pump shall be operated at its rated rpm or double strokes per minute, suction and discharge pressure. The working fluid for which the pump was designed shall be used when practicable but the fuel-oil service pumps must be tested using fuel oil only and the lube-oil service pump using lube oil. The main and auxiliary feed pumps, main and auxiliary condensate pumps, and evaporator pumps must be tested in conjunction with the system to which they are connected at design conditions

The ability of the steering gear to function with either set of two opposed cylinders in operation shall be demonstrated. Note the time required for change-over and for moving hardover to hardover (70 deg). Note the oil pressure.

Evaporating Plant

The salt-water-evaporating plant shall be operated at the designed capacity for 6 hr during the sea trials of the vessel. During the test, the evaporator shall be blown down continuously to the amount specified by the manufacturer.

The following data should be recorded as far as possible at every 30 min throughout the test: steam-pressure shell and tubes, density of the feed water, salinity of distillate, temperature of the circulating water inlet and outlet, shell temperature, quantity of fresh water (measured by taking soundings in tank to which distillate is drained).

The pumps may be tested in conjunction with this test or at some other time, but they must be tested with the evaporating plant operating at its normal rated conditions.

Whistle

The whistle shall be operated by both the mechanical and the electric control from all locations where a whistle control station is located. The whistle should be operated and then left inoperative for at least 4 hr. Particular note should be made of the sound, volume, and pitch produced by the first blast after 4 hr of inoperation. This blast should be sharp, distinct, and of volume equal to the subsequent blasts. The steam-supply pressure shall be recorded both before and during the test. Failure to meet this requirement shall be a cause for rejection.

The test shall also demonstrate the adequacy and effectiveness of moisture separation and drainage. Any carry-over of water through the whistle shall be considered an indication of inadequate drainage or ineffective moisture separation.

The automatic timing contactor shall be tested, using all the various timing cycles.

Lifting Gear

After complete installation of all machinery, equipment, and piping, the capacity, efficiency, and operation of each lifting gear shall be demonstrated if required by the U.S.M.C. representative. If required, each lifting gear shall be properly rigged for each item, the operation demonstrated, and a check made for interference. If rigging of the lifting gear is not required, each installation shall be examined for satisfactory installation.

TRIALS OF MACHINERY

Object. Machinery trials of vessels are held for the purpose of ascertaining the capabilities of the engines, boilers, and auxiliaries, either in conjunction with the contract requirements for new vessels, or to determine their efficiency under service conditions, the adequacy and workmanship of the installation, the extent of repairs necessary, the sufficiency of repairs that have been made, or the proper mode of operation and the most economical rates of performance under various conditions of service.

of vacuum, submergence, operating temperature, etc. The pumping equipment should be tested with all governors and control apparatus in place and operating. Power for the motors shall be taken using the ship's power and permanent cable installations.

The test should demonstrate that the pump is able to take its suction through the normal or emergency suction lines and deliver the required quantity of fluid at the required pressure by way of normal or emergency discharge lines, while performing its normal or emergency duties.

Motor-driven Pumps. Previous to starting the pump, the cold insulation resistance of the motor armature, motor fields, and controller wiring shall be taken. Thermometers of proper centigrade-scale range shall be attached by putty, tape, or other suitable means to the motor bearings and stator coils. Readings shall be taken before the motor is started and at each time readings are taken during the heat run.

The pump should be brought up to the rated speed and total head specified. The designed total head should be obtained by properly throttling a valve in the discharge line from the pump. This should be done for a centrifugal pump, since it is possible to place a load on the motor higher than the normal designed load if the pump is operated at its maximum rated rpm with a total head less than the designed value. This throttling should also be done for positive-displacement pumps, since this type of pump will not be loaded to its designed rating unless the total head equals the designed figure when the pump is operating at its rated speed.

Readings should be taken of all data at least every 15 min during continuous operation until the temperatures no longer show an increase. The time of continuous test shall be not less than 1 hr.

Any unusual operating conditions should be noted and carefully described on the data sheet at the time the test is run. Erratic behavior of equipment should be carefully recorded at the time of occurrence in order that any serious defect may be detected and serious failure prevented. Particular note should be made of the amount of vibration, noise, gland leakage, correctness of alignment, and adequacy of lubrication. When possible, an estimate of the amount of fluid pumped should be obtained. Where relief valves are fitted, their operation and setting should be checked.

Where no suction gages have been provided for centrifugal pumps, the static head on the pump suction should be obtained by reading the discharge pressure gage when the pump is not operating and the valve on the suction side used for the test is open. The pressure can be determined only after the pump has been properly primed, however.

At the completion of tests, field rheostats for adjustable-speed motors should be blocked so that motors cannot be operated when at full-load temperature beyond the speed or load corresponding to the rated motor output. This should be done only after the motor has reached a constant temperature.

The feeder switch on the switchboard or power-distribution panel should be opened while the motor is running at normal speed and held open until the motor stops. The switch should then be reclosed, and a note should be made on the test report as to whether or not the motor restarts.

Immediately after the motor is shut down and the feeder deenergized, the hot insulation resistance should be taken and recorded in the same manner as followed for cold insulation resistance.

The setting and operation of overload protective devices should be carefully checked during the test, preferably after the required heat run. A simulated

Trials Required by U.S. Navy. The U.S. Navy requires, in the case o new vessels, (1) a preliminary acceptance trial, which is held prior to the delivery of a vessel built under contract and (2) a final acceptance trial, which is held within a specified time after delivery of the vessel, to ascertain if there has appeared any defect, weakness, failure, or deterioration for which the contractor is responsible.

Trials Required by U.S. Maritime Commission. The U.S. Maritime Commission requires, in the case of new vessels, an acceptance trial, which is held prior to the delivery of a vessel built under contract. Final acceptance trials are generally not required; however, at the conclusion of the builder's guarantee period, usually 6 months, an inspection and examination of the machinery are made to ascertain if any defect or deficiency has appeared for which the builder is responsible.

BUILDER'S TRIALS

Before conducting acceptance trials, it is customary for the builders to give new vessels what is known as a builder's trial, in order to assure themselves that they are ready for the official trial. The builder's trial is generally an abbreviated version of the contract-acceptance trial.

DOCK TRIALS

It is generally required, as well as being the usual practice among builders, to conduct a 4- to 6-hr dock trial of machinery. Prior to starting the main engines, all auxiliary machinery necessary to the proper functioning of the main propelling plant will have been tested as required by the machinery installation tests. Previous to starting the trial, the main engines are gradually warmed up and run at slow or moderate speeds until satisfactory assurance is had that no serious difficulty will interfere with a trial of the engines at or near the highest revolutions it is possible to maintain with the vessel moored alongside the dock. On multiple-screw vessels, dock trial is generally conducted on each engine separately, in order to operate at the highest possible speed within the capacity of the mooring lines.

When undergoing dock trial, all data available are generally taken at 20- or 30-min intervals, depending on the length of the trial. Special care is taken to note the steam pressures, vacuum, lubricating-oil temperatures, condition of bearings, and general working condition of all machinery. On reciprocating engines, indicator cards are taken in both ahead and astern gear for computing horsepower and for checking valve settings. On turbine installations, torsion-meter readings are taken to determine power. Before the conclusion of the trial, the engines should be reversed and run astern for 10 to 15 min at the maximum speed obtainable, again reversed and run ahead for the remainder of the trial.

After dock trials, in the case of geared turbine-driven ships, the main gears should be carefully examined, removing all inspection plates in the gear casings that may be provided for this purpose, and a record made of the tooth contact. In the case of reciprocating-engine-driven ships, cylinder and valve-chest covers should be removed and examination made of the inside of the cylinders and the condition of the piston rings.

CONTRACT-ACCEPTANCE TRIALS

Purpose. The general purpose of a contract-acceptance trial is to determine whether the ship and her machinery will satisfactorily perform all the

requirements of the contract. In order to determine this, the ship is subjected to trials to test her speed, power, fuel consumption, general strength, and condition of the vessel and machinery. Also, from these trials, useful data for use in future designs are obtained.

Type of Trials. The acceptance trials are generally composed of the following:

1. *Progressive speed, or standardization trial.*
2. Fuel-consumption trials.
3. Maneuvering trials.
4. Steering-gear tests.
5. Anchor-windlass test.
6. Miscellaneous trials and tests.

General Procedure. It is general practice to conduct the standardization trials first, followed by maneuvering trials, miscellaneous tests, and finally the fuel-consumption trials. During all trials, the vessel should be ballasted to the contract or specified trial displacement. The ship should be at this displacement during the middle run of the high-speed group of the standardization trial, and also at the middle of the fuel-consumption trials.

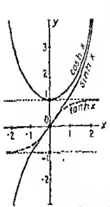
The complete trial schedule and program should be prepared well in advance, in order that all arrangements will be complete, personnel familiarized with their duties, and so that no time will be wasted while the ship is on the trial course. Trials each day should be run consecutively and without interruption, and the trial program, once approved or agreed to, should not be changed. Sudden changes in the trial schedule result in confusion among the ship and trial crews and result in poor or unsatisfactory performance.

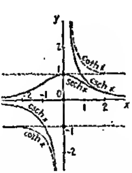
General Observations. In addition to the engineering data observed during the trials, general observations should be made of the operation of the main engines or turbines, boilers, bearings, piping systems, extent of any vibration, adequacy of light and ventilation, steadiness and seaworthiness of the vessel, and whether the vessel and machinery are well built and in accordance with contract plans and specifications and the state of completion of same.

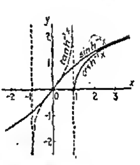
Description of Trials. 1. *Standardization Trials.* Standardization trials are conducted on new or untried vessels to determine corresponding values of speed, revolutions, and power over a reasonable range of speed (usually from one-half to maximum speed for merchant vessels, and from 9 knots to maximum for naval vessels). These trials are made at one displacement and under favorable conditions of wind and weather. From the results, it is determined whether or not the builder's guarantees have been met. Also, the designer utilizes the information in preparing subsequent designs and, from the results, the owner can generally make a close estimate of the performance to be expected in service.

Trials are conducted over a nautical mile course measured by ranges ashore. The measured mile at Rockland, Me., as shown by Fig. 2, is the best trial range on the Atlantic Coast, and the one generally used. The course off Point Vincente, Calif., is probably the best on the West Coast.

Before the start of the trials, the ship is ballasted to approximately contract displacement. Trials are started with the ship slightly heavy, so that, as fuel is expended, the ship will be at contract displacement during the high-speed runs. Generally, runs are made at slow speed first, gradually working up to high speed. A series of groups of runs are made as follows: Three

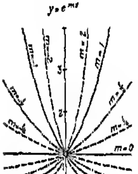


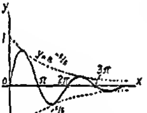




Hyperbolic functions and inverse hyperbolic functions.

FIG. 7. FIG. 8. FIG. 9.





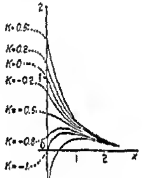


FIG. 10. FIG. 11. FIG. 12.

the points lie only approximately on a straight line, the best position for this line can usually be found by stretching a black thread among the points; or, assume a law of the form $y = mx + b$, and, by substituting in this formula n pairs of values of x and y, obtain n equations connecting the coefficients m and b; various pairs of these equations may then be solved for m and b, and the average of the results taken. Or, if great accuracy is required, all n of the equations may be solved for m and b by the method of least squares (p. 121).

If any law of the form $f(x,y) = m \cdot F(x,y) + b$ is suspected, where $f(x,y)$ and $F(x,y)$ are any expressions involving either x or y or both x and y, such a law may be tested by plotting $F(x,y)$ instead of x, and $f(x,y)$ instead of y, on rectangular cross-section paper, and seeing whether or not the points lie on a straight line. If they do, the form of the law is verified, and the values of m and b can be read from the figure as before. For example, if $y^2 = mxy + b$, a straight line will be obtained by plotting y^2 against xy. Again, if $xy = bx + my$, a straight line will be obtained by plotting y against y/x, since the equation may be written $y = b + m\,(y/x)$.

CASE 2. If a law of the form $y = cx^n$ is suspected, plot the points (x,y) on logarithmic paper (see below).

CASE 3. If a law of the form $y = c \cdot 10^{mx}$ [or $y = c \cdot e^{mx}$] is suspected, plot the points (x,y) on semi-logarithmic paper (see below).

CASE 4. If the given curve resembles the logarithmic curve, $y = \log x$, interchange x and y and proceed as in Case 3.

CASE 5. If the given curve is a wavy line, resembling a sine or cosine curve, try an equation of the form $y = a \sin bx$ or $y = a \cos bx$. If the heights of the waves diminish as x increases, try an equation of the form $y = ae^{-nx} \sin bx$. [NOTE. Any periodic function (satisfying certain simple conditions) can be expressed by a Fourier's series (p. 162)].

CASE 6. A great variety of functions can be represented approximately by a polynomial of the form $y = a + bx + cx^2 + dx^3 + ex^4 + \ldots$, the first three or four terms being usually sufficient. To determine the coefficients $a, b, c, \ldots$, most accurately, substitute in the formula all the given pairs of values of x and y, and solve the resulting equations for $a, b, c, \ldots$ by the method of least squares (p. 121).

CASE 7. Many simple curves can be represented approximately by an *equation of the hyperbolic form*, $xy = c + bx + ay$, where a, b, and c are determined by substituting the co-ordinates of three conspicuous points of the curve. The lines $x = a$ and $y = b$ are the asymptotes of the hyperbola. The equation may also be written $(x - a)(y - b) = k$, where $k = ab + c$.

Logarithmic Cross-section Paper. In this form of cross-section paper (Fig. 13), the distance from the origin to any point on the x- or y-axis is equal to the logarithm of the number written against that point. Thus, in Fig. 13 the distances (shown for clearness on two auxiliary scales X and Y) are the logarithms of the numbers written along x and y.

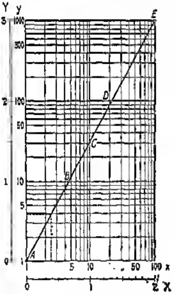

FIG. 13.

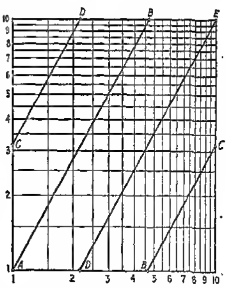

FIG. 14.

Accurately made logarithmic paper can be obtained from the principal dealers in draftsmen's supplies. Logarithmic paper can be easily constructed, in case of need, by copying the logarithmic scale from any ordinary slide rule. The actual figures along the x- and y-axes are usually left for the user to insert; in so doing, notice that the numbers . . ., 0.01, 0.1, 1, 10, 100, . . ., or such of them as may be needed to cover any given range of values, must be placed at the points of division which separate the main squares. It is often convenient, however, to omit the decimal point, num-

[g] Handwheel for 6 additional nozzles, opened 2 turns.
[h] Handwheel for 6 additional nozzles, cracked open.

consecutive runs, alternating in direction over the course and at as nearly constant rpm as possible, should be made for each speed point desired below full speed, and five consecutive runs, alternating in direction, should be made at the highest speed attainable. Each series of runs at the same speed *should be uninterrupted and performed in sequence. If it should be found* necessary to throw out any run, a sufficient number of additional runs should be made at that speed to produce at least three consecutive runs alternating in direction over the course.

The runs over the course should be made back and forth over the same water. Between runs, the ship should be taken well away from the measured *course, so as to ensure the attainment of steady speed on the next run.* The approach should be at least 3 miles, and the ship should be straightened on the course while at least 1 mile from the range as shown by Fig. 2.

During each group of runs, not only when running the measured course but throughout the intervals between runs, conditions should be maintained

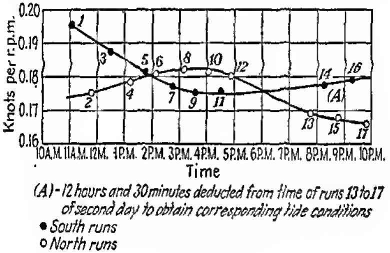

Fig. 3.—Standardization runs.

uniform; *i.e.*, the revolutions or power should be constant. On vessels equipped with governors, the desired rpm can be set and will be maintained irrespective of changes in steam pressure, etc. For turbine installations not equipped with governors, it is good practice to keep the number of nozzles open, the turbine inlet pressure and vacuum constant, and let the revolutions vary. Also, if the turbine is equipped with bleeders, these should not be changed. On reciprocating-engine installations, the cutoff and steam pressure and vacuum should be maintained constant during each group of runs.

The following data for each run should be recorded: (1) elapsed time on the course, (2) total revolutions of each engine while on the course, (3) indicator cards or torsion-meter readings at frequent intervals while on the course, (4) thrust measurements at frequent intervals, (5) wind direction and velocity. Generally, all engineering data are also observed once during each run.

At the end of *each run, computations should be made and the following* determined: (1) speed in knots, (2) rpm, (3) shp, (4) thrust, (5) shp/rpm^3, (6) speed/rpm, (7) thrust/rpm^2. Plots should be maintained of items (2), (3), and (4), on a base of item (1). Also, items (5) and (7) should be plotted

sumption trials are generally run at normal and maximum designed shp and occasionally at reduced powers. Guarantees are made only at normal shp. For naval vessels, fuel-consumption trials are run at approximately 5-knot intervals from about 10 knots to maximum power, and guarantees are made at each point. Fuel-consumption trials involving guarantees generally last from 6 to 8 hr for merchant ships and 4 hr for naval vessels.

The trials are generally conducted at contract displacement in open sea. Readings of gages, thermometers, revolution counters, and all other trial-

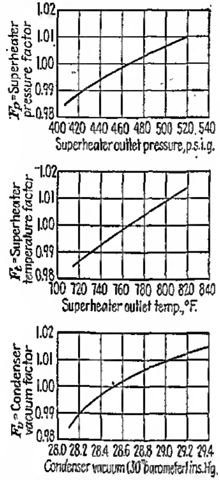

FIG. 6.—Fuel rate correction factors.

trip instruments are made at least every ½ hr during the trials and, in addition, the torsion meters are read about every 3 min so as to assure a continuous record of torque and revolutions. All meters, gages, tanks, and special equipment required in connection with the trials are tested or calibrated prior to the trials. Also, fuel-oil meters in addition to the regular ship's meter are generally used and are calibrated before and after the trials. Fuel-oil samples are taken during the trials and analyzed for heating value, etc. The trial data may be analyzed and reduced to standard conditions by a method similar to that described in a discussion appearing in the *Trans. Soc. Nav. Arch. and Mar. Engs.*, 1940, p. 354.

[j] No steam used during trials, since stand-by fuel-oil service pump, which was operating as a booster pump in order to meter oil accurately, used as equivalent amount of steam.

[k] Not in use.

[l] In use 1 hr during trial to make up lost feed water.

The results of fuel-consumption trials of naval vessels are accepted as run, the only corrections being those required for ship's heating, meter calibrations, and heat content of the fuel oil. However, the U.S. Maritime Commission has required, in all recent trials involving guarantees, that corrections be made for main steam pressure, temperature, and condenser vacuum differing from the design, in addition to the usual corrections for ship's heating, meters, and heating value of the oil. In order to accomplish this, correction factors were prepared by the contractor and approval secured before trials. The factors consisted of a set of curves that gave correction factors to be applied to the fuel rate for variations from designed boiler pressure and temperature and condenser vacuum, such as shown by Fig. 6, for designed conditions of 465 psi gage, 765 F, and 28.5 in. vacuum.

3. *Maneuvering Trials.* These trials are conducted to demonstrate the maneuvering ability of the vessel and generally consist of the following: (1) a test to determine the diameter of the turning circle of the vessel with the rudder in the hardover position, (2) a test to demonstrate the ability of the vessel to go from full speed ahead to full speed astern, (3) a backing test at full astern power to demonstrate that the engines will develop the specified astern power without undue heating, (4) a test to demonstrate the ability of the vessel to go from full speed astern to full speed ahead, (5) a test to determine the time required to go from full speed ahead to dead stop. These tests are usually conducted in the order named.

Other maneuvering trials are sometimes specified, such as a maneuver to determine the time required for the ship's heading to change a specified number of degrees from a base course with a specified amount of helm.

4. *Steering-gear Tests.* These tests are made to show that the main steering gear is capable of moving the rudder under all conditions. Generally the contract specifies that the steering gear is to move the rudder from hardover to hardover in a specified time with the vessel going ahead at full speed and also from hardover to hardover when developing full astern power without exceeding a specified oil pressure in the steering-gear cylinders.

Emergency steering-gear tests are also conducted to meet the requirements of the classification societies. The rudder must be moved from hardover to hardover, using emergency steering gear, with the vessel proceeding at 7 knots or at half speed, whichever is greater.

5. *Anchor-windlass Test.* This test is required to demonstrate the ability of the anchor windlass to handle the anchor under any condition. Generally, the contract specifies that the windlass will be tested in a specified depth of water, letting go both anchors at the same time, under control of the brake, and stopping at various depths; also hoisting one anchor with a specified length of chain at a specified speed, and hoisting both anchors with a specified length of chain at a specified speed.

6. *Miscellaneous Trials.* Miscellaneous trials, including torsiograph test, water-rate test, boiler-overload test, astern standardization trial, may be specified on certain types of vessels.

Generally, the first vessel of each class or type is given a torsiograph test to demonstrate that no serious torsional vibration exists in the main propelling shaft and mechinery. This test consists of operating the machinery at various rpm near the criticals and measuring the torsional vibration by means of a torsiograph.

When guarantees of water rates of the main propelling unit are made, the builder generally conducts a water-rate test on one ship to check the engine

manufacturer's guarantees. During this test the condensate is weighed or metered, the power is measured by means of a torsion meter, and the steam conditions and vacuum are accurately determined. During this test the turbine is operated nonbleeding and noninduction.

It is the general practice on merchant vessels that have two boilers to specify that each boiler shall be good for 50 percent overload under emergency conditions in order that three-fourths power may be maintained with one boiler out of service. Therefore, a test is generally made to demonstrate that the boiler is capable of operating at this load. If the vessel is equipped with more than two boilers, then the overload is less. On naval vessels, the overload is usually 20 percent, and a test at this rating is generally made on one vessel of each class.

On special types of vessels, such as airplane carriers, it is essential to know the speed that can be maintained astern. Therefore, these vessels are standardized in the same manner as described above. Other types of naval vessels are generally run over the measured mile at maximum astern power to determine their approximate astern speed.

TRIALS OF S. S. "RED JACKET"

The requirements for and information obtained from acceptance trials may be illustrated from the following description* of the trials of the S. S. "Red Jacket." This ship is a U.S. Maritime Commission, C2-type vessel, having a single screw driven by double reduction-geared turbines supplied with steam from two water-tube D-type boilers and fitted with electric auxiliaries and automatic controls.

The contract required the following trials for this vessel:

Standardization Trials. The trials prescribed in the contract included

1. Standardization trial at deep draft, during which the vessel shall be loaded to a molded mean draft of 25 ft 9 in. with due regard to proper trim. Three consecutive runs will be made at each of the following speeds: at about 9, 12, 14, and 15½ knots, and five consecutive runs with the propelling machinery developing maximum shaft horsepower.

2. Standardization trial at light draft, during which the vessel shall be ballasted to a molded draft, approximately as follows:

Forward 16 ft 2 in., aft 22 ft 2 in., mean 19 ft 2 in. This condition of trim shall be obtained by the use of deep tanks, trim tanks, and such oil or salt water in the double-bottom tanks or by the use of such form of ballast as is found necessary. The speeds at which this trial shall be run will be at the number of revolutions established from model-tank experiments corresponding to 9, 12, 14, and 15½ knots and the number of rpm shown by model-tank experiments which can be obtained when developing the normal shaft horsepower of 6,000 under the above conditions of loading.

The results of these trials are given in Tables 2 and 3, and the average data are plotted on Fig. 7.

Endurance and Fuel-economy Trials. The contract required an 8-hr endurance trial in open sea in deep water, while having a molded draft of 16 ft 2 in. forward, 22 ft 2 in. aft, mean 19 ft 2 in. During this endurance trial the engines are to develop 6,000 shp, and the fuel consumption for all purposes will be carefully determined.

* Data from "Report of Progressive Speed at Deep and Light Draft, Maneuvering, Endurance and Fuel Economy Trials of the Single Screw Cargo Ship S. S. Red Jacket," U.S. Maritime Commission Trial Board, September, 1939.

On this trial the following auxiliaries shall be in operation:

1. All auxiliaries necessary to the main propelling plant during the trial
2. The refrigerating plant.
3. The electric generating plant to be run at not less than 170 kw.

Also, the specifications stated that "When the ship is at sea under normal operating and weather conditions, developing 6,000 shp and with one generator developing the required electrical load at this power (but not less than 170 kw), normal use of steam in heating of sanitary water and fuel oil, a sea-water temperature of 75 F and the boilers operated with 18,500 Btu

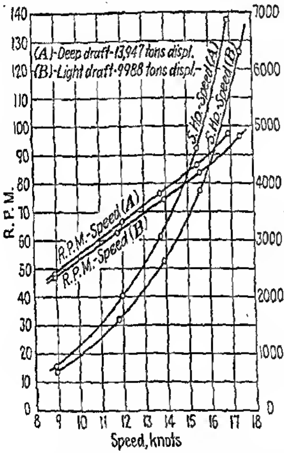

FIG. 7.—Standardization results.

fuel oil, an over-all consumption of 0.60 lb fuel oil per shp per hr is to be guaranteed."

As a development of the contract, owing to design changes, the 170 kw referred to above was changed to 185 kw. Also, it was agreed that the 8-hr endurance trial should consist of a 2-hr endurance trial at maximum designed shaft horsepower (6,600) and a 6-hr fuel-economy trial at normal designed shaft horsepower (6,000). Also, at the request of the U.S. Maritime Commission, it was agreed to run three trials of 2-hr duration each at reduced power.

The results and data obtained during these trials are given in Table 4.

Backing and Maneuvering Tests. In order to determine the backing and maneuvering ability of the vessel, the contract prescribed the following test:

INDEX

(For abbreviations used, see pp. xiii–xviii)

1. A ½-hr backing test at full astern power to demonstrate that the engines will develop the specified astern power without undue heating.

During this test the machinery operated without overheating at 62.4 rpm, developing 2,556 shp and a thrust of 60,400 lb, with steam conditions as follows:

Astern inlet pressure, psi gage	220
Astern inlet temperature, deg F	490
Exhaust temperature, deg F	103

2. A test to determine the ability of the vessel to go from full speed ahead to full speed astern and the time required to do so and the ahead reach.

With the vessel going ahead at normal speed (96 rpm) a signal was given for full astern power. The vessel was judged dead in the water 4 min 15 sec later. The plotted track showed an ahead reach over the ground of 1,680 yd, no correction being made for current.

3. A test to determine the ability of the vessel to go from full sternway to full speed ahead and the time required to do so and the stern reach.

With the vessel going astern at full astern power (67 rpm) a signal was given for full ahead power. The plotted track shows an astern reach of 620 yd in 3 min, no correction being made for current.

4. A test to determine the time required from full speed ahead to a dead stop.

With the vessel going ahead at normal speed (97 rpm), a signal was given to remove all power from the shaft. The vessel was judged dead in the water 39 min later. The plotted track shows a distance of 5,680 yd in 39 min.

5. A test to determine the diameter of the turning circle with the rudder in the hardover position, the speed of the vessel during this test to be that attainable with the propelling machinery developing 6,000 shp.

Turning circles were made with hard-left and hard-right rudder. The diameter was estimated as five ship lengths for each circle. The time to swing the ship's head through 360 deg was 6 min for the left circle and 6 min 37 sec for the right circle.

Steering-gear Tests. The tests prescribed in the contract included

1. Movement of the rudder from hardover to hardover (through 70 deg of arc) in 30 sec at full speed ahead.

2. Movement of the rudder from hardover to hardover at full speed astern in no specified time, without exceeding 1,500 psi oil pressure.

3. Movement of the rudder through full travel by means of the emergency gear (tackles led to the afterdeck winch).

Test 1 was performed with the vessel steaming ahead at full speed (96 rpm). The rudder reached the maximum travel specified (70 deg) in 30 sec, the required rate. The maximum pressure indicated was 1,000 psi.

Test 2 was performed with the vessel steaming astern at full speed (67 rpm). Rudder travel in this case was from 34½ deg left to 35½ deg right, a total of 70 deg in 25 sec. The maximum pressure was 850 psi.

Test 3 was performed with the vessel steaming ahead at 46 rpm. The emergency tackles were rigged in about 30 min by eight men. The rudder was moved from 34 deg right to 34 deg left in 30 sec.

Anchor-windlass Test. The tests specified for the anchor gear in the contract included

1. Letting go both anchors at the same time.

2. Hoisting one anchor with at least 30 fathoms of chain at a speed of 30 fpm.

3. Hoisting two anchors with at least 15 fathoms of chain attached to each anchor at a rate of 20 fpm.

Test 1 was performed by dropping both anchors in 32 fathoms of water.

Test 2 was performed at a chain speed of 32.1 fpm, 240 volts, 110 amp average current.

Test 3 was performed at a chain speed of 25.7 fpm, 240 volts, 160 amp average current.

bering each square independently from 1 to 10. The length of the side of one square is called the *unit* or *base* of the logarithmic paper; the larger the unit, the finer the possible subdivisions of the scale.

To plot a point (x,y) on logarithmic paper, for example, the point (3,5), means to find the point of intersection of the vertical line marked $x = 3$ and the horizontal line marked $y = 5$. In interpolating between two lines, account should be taken of the fact that the divisions are not of uniform length.

Any equation of the form $y = cx^n$ when plotted on logarithmic paper will be represented by a straight line whose slope is n. For, if $y_1 = cx_1^n$ and $y_2 = cx_2^n$, then $y_1/y_2 = (x_1/x_2)^n$, or $(\log y_1 - \log y_2)/(\log x_1 - \log x_2) = n$. The slope must be measured by aid of an auxiliary *uniform* scale.

EXAMPLE. Let $y = x^{3/2}$. When $x = 1$, $y = 1$; plot this point A on the logarithmic paper, and draw the straight line AB with a slope equal to $\frac{3}{2}$ (Fig. 13). By the aid of this line, the value of y for any value of x between 1 and 100 can be read off directly; for example, if $x = 2.50$, $y = 3.95$, as shown by dotted lines, so that $(2.50)^{3/2} = 3.95$. To find the value of y for any value of x outside this range, note that moving the decimal point 2 places in x is equivalent to moving it 3 places in y. The line shown in Fig. 13 is thus equivalent to a complete table of three-halves powers.

It will be noticed that this line crosses four squares of the logarithmic paper. By superposing these four squares the whole diagram may be condensed into a single square (Fig. 14), in which, however, the scales for x and y now give only the sequence of digits in the answer, the position of the decimal point having to be determined by inspection.

To determine whether a given set of values, x and y, satisfies a law of the form $y = cx^n$, plot the values on logarithmic paper, and see whether they lie on a straight line; if they do, then the given values satisfy a law of this form; moreover, the slope of the line gives the value of n, and the value of y when $x = 1$ gives the value of c.

If the plotted points fail to lie exactly in line, but form a curve slightly concave upward, try subtracting some constant b from all the y's, that is, move each point downward a distance equal to b units of the y-scale at that point. If it proves possible to choose b so that the resulting points lie in line, then the original values obey a law of the form $y - b = cx^n$, where n is again the slope of the line, and c is the value of $y - b$ when $x = 1$. (Conversely, if the curve is concave *downward*, try *adding* b to all the y's; that is, move each point *upward*; if the new points lie in line, the original values obey a law of the form $y + b = cx^n$.) Another method of "straightening" the curve consists of adding some constant, $\pm a$, to all the values of x, which has the effect of shifting all the points to the right or left (by varying amounts); if this method succeeds, the original values obey a law of the form $y = c(x + a)^n$.

Semi-logarithmic Cross-section Paper. This form of paper (Fig. 15) has a logarithmic scale along y and a uniform scale along x. The "**scale value**," k, of the paper is the number which stands, on the x-axis, at a distance from the origin equal to the width of one of the main horizontal strips. Thus, in Fig. 15, each number shown along the auxiliary scale Y is the logarithm of the corresponding number along y; and each number shown along the auxiliary scale X is $1/k$th of the corresponding number along x (here $k = 5$). The number k, which may be chosen at pleasure, should be taken equal to some simple integer, as 1, 2, or 5, or some integral power of 10.

In preparing the paper for use it is important to notice that the numbers . . ., 0.01, 0.1, 1, 10, 100, . . . (or such of them as may be needed in any given case) must be placed along the y-axis at the points which mark the main lines of division between the horizontal strips; while the numbers . . ., $-2k$, $-k$, 0, $+k$, $+2k$, . . . (or such of them as may be needed) must be placed along the x-axis at uniform intervals, each interval (from 0 to k, from k to $2k$, etc.) being equal to the width of one of the main horizontal strips. The width of one of these strips is called the *unit* or *base* of the semi-

logarithmic paper; the larger the unit, the finer the possible subdivisions of the scale.

To plot a point (x,y), as $x = 3$, $y = 5$, on semi-logarithmic paper means to find the point of intersection of the vertical line marked $x = 3$ with the horizontal line marked $y = 5$.

Any equation of the form $y = c \cdot 10^{mx}$ [or $y = c \cdot e^{mx}$] when plotted on semi-logarithmic paper with scale value k, will be represented by a straight line whose slope is km [or $0.4343\, km$.]. By a suitable choice of the scale value k, any given range of values of x can be brought within the size of the paper. Note that $e = 10^{0.4343}$.

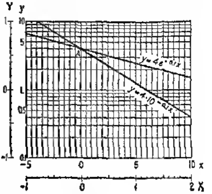

FIG. 15.

EXAMPLE. Given $y = 4 \cdot 10^{-0.5x}$ [or $y = 4 \cdot e^{-0.1x}$]. In Fig. 15, when $x = 0$, $y = 4$. By plotting this point (A) on the semi-logarithmic paper, with scale value 5, and drawing through it a straight line with slope equal to -0.5 [or -0.217] a graphical representation is obtained from which, for any value of x, the corresponding value of y can be read off. If it is desired to condense the figure, several horizontal strips may be superposed on a single strip; this of course renders the decimal point in the y-scale undetermined (unless a separate y-scale is provided for each section of the graph).

In order to determine whether a given set of values of x and y satisfy a law of the form $y = c \cdot 10^{mx}$ [or $y = c \cdot e^{mx}$], plot the values of x and y on semi-logarithmic paper, with a suitable scale value k, and see whether they lie on a straight line; if they do so, the law is satisfied, and the values of m and c may be found as follows: m = the slope of the line divided by k [or the slope of the line divided by $0.4343k$], and c = the value of y when $x = 0$.

If the plotted points fail to lie exactly in line, but form a curve slightly concave upward, try subtracting some constant b from all the y's, and plot the values thus modified; if b can be so chosen that the revised points lie in line, then the original values obey a law of the form $y - b = c \cdot 10^{mx}$ [or $y - b = c \cdot e^{mx}$], where m and c are to be found as before. If the curve is concave downward, add b, instead of subtracting; and replace $y - b$ by $y + b$ in the law.

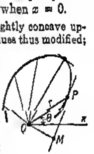

FIG. 16.

Curves in Polar Co-ordinates. Any function, r, of a single variable, θ, can be represented by a curve in polar co-ordinates (p. 137). Lay off the given values of θ as angles, the initial line Ox running toward the right, and the counterclockwise direction about the origin being taken as positive. Along the terminal side of each angle θ, lay off the corresponding value of r, forward if r is positive, backward if r is negative; and pass a smooth curve through the points thus determined.

The rate of change of r with respect to θ at a given point P is represented graphically as follows (Fig. 16): On the tangent at P drop a perpendicular OM from the origin: then $r(MP/OM)$ represents the rate of change, $dr/d\theta$, provided θ is measured in radians. Specially ruled polar co-ordinate paper is supplied by dealers in drafting supplies.

EQUATIONS INVOLVING THREE VARIABLES

The Surface $z = f(x, y)$. Any function, z, of two variables, x and y, may be represented by a surface, as follows: Plot the given pairs of values of x and y as points in a horizontal x, y plane, called the base plane; at each of these points erect an ordinate, parallel to a vertical axis z, and representing by its length the value of z at that point. Then conceive a smooth surface

passed through the extremities of these ordinates: this surface is said to represent the function. In practice, the ordinates may be made by implanting stiff vertical rods in a horizontal board of soft wood which serves as the base plane; the surface may then be constructed by filling in the spaces with plaster of Paris. Or, more simply, pieces of cardboard may be cut out to represent parallel plane sections of thn surface, and then stood on edge in slots cut in the board to receive them. The units employnd along x, y, and z need not he equal to each other.

Contour-line Charts. All the points of a surface $z = f(x, y)$ which are at any given height above the base plane form a curve on the surface, called a contour line of the surface. If each of these contour lines be projected on the base plane, and each labeled with the value of z to which it corresponds, a complete representation of the function $z = f(x, y)$ is obtained, all in one plane. A topographical map, with contour lines showing elevations above the sea, and a weather map, with contour lines showing barometric pressure, are familiar examples. If there are several values of z corresponding to any given point (x, y), there will be several contour lines whose projections pass through that point.

Contour-line Charts for Simultaneous Equations [of the form $z = f(x,y)$, $w = F(x,y)$]. In Fig. 17, plot the function $z = f(x,y)$ by contour lines on an x,y plane, and plot the function $w = F(x,y)$ by contour lines on the same x,y plane. Then every point on the diagram (either directly or by interpolation) is the intersection of four curves—an x-curve, a y-curve, a z-curve, and a w-curve. Here, by "curve" is meant any line, straight or curved. By the aid of such a diagram, when the values of any two of these four variables are given, the values of the other two can be found. The method of use consists simply in entering the diagram along the two given curves (or lines), tracing them to their point of intersection, and then coming out again along the two curves (or lines) whose values are required. The best manner of numbering the curves is indicated in the figure.

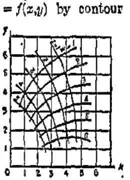

FIG. 17.

ALIGNMENT CHARTS

Alignment Charts for Three Variables, t, u, v. Any relation between three variables, t, u, v, which can be thrown into one of the forms listed in later paragraphs, can be represented graphically by a very convenient form of diagram called an alignment chart. In the simplest form of an alignment chart for three variables there are three scales (straight or curved), along which the values of the three variables, t, u, v, are marked in such a way that any three values of t, u, v which satisfy the given equation are represented by three points which lie in line. Hence, if the values of any two of the variables are given, the corresponding value of the third can be found by simply drawing a straight line through the two given points and reading the value of the point where it crosses the third scale.

The most important methods of constructing alignment charts for three variables are described below. Where several methods are applicable in a given case, the best one must be determined largely by trial. For further information, see M. d'Ocagne, "Traité de Nomographie," Gauthier-Villars, Paris; Carl Runge, "Graphical Methods," Columbia University Press; J. B. Peddle, "Construction of Graphical Charts," McGraw-Hill; J. Lipka, "Graphical and Mechanical Computation," Wiley; Hewes and Seward, "The Design of Diagrams for Engineering Formulas and the Theory of Nomography," McGraw-Hill.

Method 1. Given, an equation which can be thrown into the form

$$f_1(u) + f_2(v) = f_3(t),$$

where $f_1(u)$ is a function of u alone, $f_2(v)$ a function of v alone, etc. An alignment chart may be constructed as follows:

Choice of Moduli to Fit Size of Paper. Let $f_1(u')$ be the smallest and $f_1(u'')$ the largest value of $f_1(u)$ likely to be needed, and let h be the height of the available space on the paper. Then find a simple number, m_1, such that m_1 times $f_1(u'') - f_1(u')$ shall not exceed h. Similarly, find a simple number m_2 such that m_2 times $f_1(v'') - f_1(v')$ shall not exceed h.

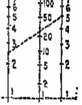
Also, compute a third modulus, m_3, by the formula

$$m_3 = (m_1 m_2)/(m_1 + m_2).$$

Construction of the First Two Scales. Draw two parallel vertical axes, at any distance, k, apart. On the first axis, marked u, starting with any convenient origin, lay off the distances $x = m_1 f_1(u)$ for successive values of u, *labeling each point thus plotted with the corresponding value of u.* Similarly, on the second axis, marked v, starting with any convenient origin, lay off $y = m_2 f_2(v)$ for successive values of v, labeling each point with the corresponding value of v. The u-scale and the v-scale are thus completed.

Construction of the Third Scale. Draw a third line, t, parallel to the first two lines, dividing the distance k in the ratio m_1/m_2; that is, the distance from u to t is $m_1 k/(m_1 + m_2)$. Compute the value t_0 corresponding to any convenient values u_0 and v_0, and label with this value, t_0, the point where the t-axis is cut by a straight line joining the points u_0 and v_0. Using this point t_0 as an anchorage, lay off along the t-line the scale determined by $z = m_3 f_3(t)$ where $m_3 = (m_1 m_2)/(m_1 + m_2)$. The third scale is thus completed, and the chart is ready for use.

Note that the units of measurement for x, y, and z (which do not appear on the completed chart) must of course be the same. Note also that to ensure accuracy on the third scale, especially if the modulus m_3 is small, it is well to compute more than one anchorage point, t_0.



$uv^{1.41} = t$

FIG. 18.

The construction is greatly facilitated by the use of previously constructed uniform and logarithmic scales with various moduli.

EXAMPLE (Fig. 18). Let $uv^{1.41} = t$, for a range of values of u and v between 1 and 10. By taking the logarithm of both sides, reduce the equation to the form $\log u + 1.41 \log v = \log t$. Here $f_1(u) = \log u$, $f_2(v) = 1.41 \log v$, $f_3(t) = \log t$. For a height of paper $h = 10$, and a width $k = 5$, we may take $m_1 = 10$ and $m_2 = 10/1.41 = 7.09$; whence $m_3 = 4.15$ and $m_1 k/(m_1 + m_2) = 2.92$. Hence the chart is readily constructed, as shown.

Method 1a. Method 1 may be readily extended to equations of the form

$$f_1(u) + f_2(v) + f_3(w) = f_4(t),$$

involving four variables, t, u, v, w.

Let $f_1(u) + f_2(v) = q$ and chart this equation by Method 1. Then chart the equation $q + f_3(w) = f_4(t)$ by the same method, using as one of the scales the q-scale already drawn. (The q-scale need not be graduated; the position of the q-axis is all that is important.) In reading the completed chart, we use two index lines, one joining points u and v, and cutting the q-axis in an (unlabeled) point q; the other joining points w and t, and cutting the q-axis in the same (unlabeled) point q. Thus when any three of the four variables are given, the fourth can be found.

A further extension to equations of the same form involving five or more variables is obvious.

EXAMPLE (Fig. 19). Let $t = w\sqrt{uv}$ whence $\frac{1}{2}\log u + \frac{1}{2}\log v + \log w = \log t$. Here $f_1(u) = \frac{1}{2}\log u$, $f_2(v) = \frac{1}{2}\log v$, $f_3(w) = \log w$, and $f_4(t) = \log t$.

Method 2. Given, an equation which can be thrown into the form

$$f_1(u) = f_2(v).f_3(t)$$

where $f_1(u)$ is a function of u alone, $f_2(v)$ a function of v alone, etc. First, choose two "moduli" m_1 and m_2 (to fit size of paper) exactly as in Method 1.

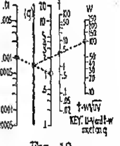


FIG. 19.

Secondly, draw two parallel vertical axes, AX and BY, oppositely directed, the diagonal line AB being of any convenient length k. With A and B as origins, lay off along these axes the distances

$$x = m_1f_1(u) \text{ and } y = m_2f_2(v),$$

for successive values of u and v, respectively, and label each point thus plotted with the corresponding value of u (or v). The u and v scales are thus completed.

Thirdly, on BY select a point F at any convenient distance, l, from B; compute an auxiliary modulus, n, by the formula $n = lm_1/m_2$; and lay off along AX an auxiliary scale, $x' = nf_3(t)$ for successive values of t, marking each point (temporarily) with the corresponding value of t. Then transfer this auxiliary scale to the axis AB by means of projecting lines drawn through the point F, marking each point (permanently) with the corresponding value of t. The t-scale, along the axis AB, is thus completed, and the chart is ready for use.

As a check, note that along the t-axis, the distance z from A to any point labeled t should be given by

$$z = km_1f_3(t)/[m_1f_3(t) + m_2].$$

Indeed the points of the t-scale may be laid down independently by the use of this formula, if desired, stead of by the graphical method above described.

This type of chart is known as a *Z-chart*.

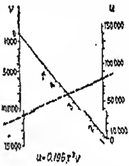

FIG. 20.

EXAMPLE (Fig. 20). Let $u = 0.196t^2v$, where u is to range from 0 to 150,000 and v from 0 to 15,000. The equation may be written $u = (10v)(0.0196t^2)$.

Here $f_1(u) = u$, $f_2(v) = 10v$, $f_3(t) = 0.0196\,t^2$.

The theory underlying Methods 1 and 2 depends only on simple properties of similar triangles. The following methods are based on certain standard equations of the straight line in analytical geometry, and the notation in what follows has been suggested by the form of these equations.

Notation. In each of the equations which follow, U stands for any function of u alone, V for any function of v alone, and $F_1(t)$, $F_2(t)$ for any functions of t alone. Any of these functions may reduce to a constant. The axes of x, y, and y' which are mentioned are of merely temporary use in constructing the diagram, and the letters x, y, y' should not be written on the chart. It is not necessary that the axes be at right angles, provided the x of a point is always measured parallel to the x-axis, and its y parallel to the y-axis.

Method 3. Given, an equation which can be thrown into the form

$$U{\cdot}F_1(t) + V{\cdot}F_2(t) = 1,$$

where, for the given range of values of u and v, the largest variations in U and V are less than a certain number m.

Draw a pair of (temporary) x,y axes (Fig. 21), and through the point $x = 1$ draw a third axis, which may be called the axis of y', parallel to the axis of y. In ordinary cases, the unit of measurement along x should be nearly equal to the full width of the paper. Now choose a unit for y and y' such that m times this unit will about equal the height of the paper, and plot, in the usual way, the points (x,y) given by

$$x = \frac{F_2(t)}{F_1(t) + F_2(t)}, \quad y = \frac{1}{F_1(t) + F_2(t)},$$

FIG. 21.

labeling each point with the value of t to which it corresponds. Connect these points by a smooth curve, which gives the t-scale of the diagram. [If $F_1(t)/F_2(t)$ = a constant, the t-scale will prove to be a straight line parallel to the y-axis.]

Then, using the same units as above, plot along y the points given by $y = U$, labeling each point with the corresponding value of u; and plot along y' the points given by $y' = V$, labeling each of these points with the corresponding value of v. This gives the u- and v-scales of the diagram. The three scales being thus constructed, the x-axis may now be erased, and the diagram is ready for use. Any three points t, u, v which lie in line correspond to three values of t, u, v, which satisfy the given equation. The numbering on each scale should be shown at sufficiently frequent intervals to permit of easy interpolation.

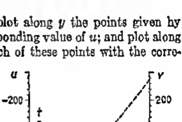

FIG. 22.

EXAMPLE (Fig. 22). Let $v = ut + 16t^2$, which reduces to the form $(-u/16)(1/t) + (v/16)(1/t^2) = 1$. Here $U = -u/16$, $V = v/16$, $F_1(t) = 1/t$, $F_2(t) = 1/t^2$ and $x = 1/(1+t)$, $y = t^2/(1+t)$.

NOTE. If $m = \infty$, values of u and v which give large values of U and V cannot be shown within the limits of the paper. In such cases, the chart may be supplemented by a second chart, made according to Method 4, below.

Method 4. Given, an equation which can be thrown into the form

$$\frac{F_1(t)}{U} + \frac{F_2(t)}{V} = 1,$$

where, for the given range of values of u and v, the largest variation in U is less than a certain number m, and the largest variation in V is less than a certain number n.

Draw a pair of temporary x,y axes, and having chosen a unit for the x-axis equal to about $(1/m)$th of the width of the paper, and a unit for the y-axis equal to about $(1/n)$th of the height, plot the points (x,y) given by

$$x = F_1(t), \quad y = F_2(t),$$

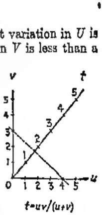

FIG. 23.

labeling each point of this curve with the value of t to which it corresponds. Connect these points by a smooth curve, which gives the t-scale of the diagram. [If $F_1(t)/F_2(t)$ = a constant, the t-scale will be a straight line through the origin.]

Then, using the same units as above, plot along x the values of U, labeling each point with the corresponding value of u; and plot along y the values of V, labeling each point with the corresponding value of v.

Draw axes x, y, and y' as in Method 3, and plot the network of curves given by the equations

$$x = \frac{F_2(r,s)}{F_1(r,s) + F_2(r,s)}, \qquad y = \frac{1}{F_1(r,s) + F_2(r,s)}.$$

[To do this (Fig. 25), find the point (x,y) that corresponds to each given pair of values of r and s, by direct substitution in the equations for x and y. Connect all the points for which $r = 1$ by a curve, and label it $r = 1$; connect all the points for which $r = 2$ by another curve, and label it $r = 2$; etc. This gives the family of r-curves. Similarly, through all the points for which $s = 1$ draw a curve labeled $s = 1$; through all the points for which $s = 2$ draw a curve labeled $s = 2$; etc. This gives the family of s-curves, intersecting the family of r-curves. Note, however, that if it is possible to eliminate s (or r) from the equations that give x and y, the resulting equation in x, y, and r (or x, y, and s) can often be plotted directly for each given value of r (or of s).]

Next, construct the u- and v-scales along the axes of y and y' as in Method 3. [The letters x, y, and y', and the units used in plotting along these axes, should be omitted from the finished diagram, as should also the axis of x.]

In the chart, as thus completed, any three points, (r,s), u, and v which lie in a straight line, correspond to values of r, s, u, v which satisfy the given equation. Hence, when any three of these four values are given, the fourth can be found from the chart.

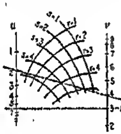

FIG. 25.

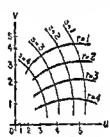

FIG. 26.

Method 4a. Given, an equation of the form

$$\frac{F_1(r,s)}{U} + \frac{F_2(r,s)}{V} = 1.$$

Draw axes of x and y as in Method 4, and plot the network of curves given by

$$x = F_1(r,s), \; y = F_2(r,s).$$

To do this, follow the plan outlined for a similar case under Method 3a, labeling each curve of the r-family (Fig. 26) with the corresponding value of r, and each curve of the s-family with the corresponding value of s. Next, construct the u- and v-scales along the x- and y-axes, precisely as in Method 4. Then any three points, (r,s), u, and v, which lie in a straight line correspond to values of r, s, u, v which satisfy the given equation.

Method 5a. Given, an equation of the form

$$F_2(r,s) = V \cdot F_1(r,s) + U.$$

Draw axes of x and y, as in Method 5, and plot the network of curves given by $x = F_1(r,s)$, $y = F_2(r,s)$, following the plan outlined for a similar case under Method 3a, and labeling each curve of the r-family (or s-family) with the value of r (or s) to which it corresponds. Next, construct the u-scale

Method C. Given, an equation of the form

$$R - S = \frac{V}{U}.$$

In Fig. 30, take a pair of axes, x,y, and through the point $x = 1$ draw a third axis, y', parallel to y. Also, take a second pair of axes, x_2,y_2, parallel to (or coinciding with) the axes of x and y. Having chosen a suitable unit for x and x_2, and a suitable unit for y, y', and y_2, lay off the values of R and

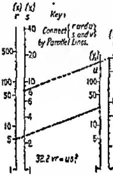

Fig. 28.

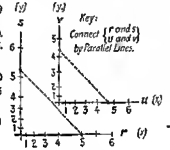

Fig. 29.

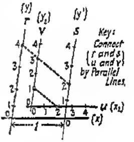

Fig. 30.

S along y and y', respectively, labeling each point with the value of r or s to which it corresponds; and lay off the values of U and V along x_2 and y_2, labeling each point with the value of u or v to which it corresponds. Then if the line joining two points r and s is parallel to the line joining two points u and v, the four values r, s, u, v will satisfy the given equation.

For further examples, see R. C. Strachan, "Nomographic Solutions for Formulas of Various Types," Trans. Am. Soc. Civil Engineers, vol. 78, 1915.

VECTOR ANALYSIS

Many problems involving directed magnitudes can be advantageously treated by the methods of vector analysis. The following is a brief summary of the principal definitions and formulæ.

A set of arrows, each arrow having a given *length* and pointing in a given *direction*, is called a set of **vectors**, provided they combine by addition according to the parallelogram law (see below). Notation: $\mathbf{a}$ or a for a vector; a or $|\mathbf{a}|$ for its length. Two "free" vectors are equal if they have the same length and point in the same direction; two "sliding" vectors are equal if they have the same length and direction, and also lie in the same line.

A **scalar** is any real number, positive, negative, or zero.

Addition of vectors.—If an arrow $\mathbf{a}$ is immediately followed, tip to tail, by a second arrow $\mathbf{b}$, then the arrow which runs from the beginning of $\mathbf{a}$ to the end of $\mathbf{b}$ is called the **sum** of $\mathbf{a}$ and $\mathbf{b}$, denoted by $\mathbf{a} + \mathbf{b}$. Conversely, if $\mathbf{a} + \mathbf{x} = \mathbf{b}$, then $\mathbf{x} = \mathbf{b} - \mathbf{a}$. The laws of operation for $+$ and $-$ are the same as in ordinary algebra (pp. 112, 124). If m is a scalar, then $m\mathbf{a}$ means a vector having the same direction as $\mathbf{a}$, and m times its length.

This gives the u- and v-scales of the diagram. On the chart as thus completed, any three points t, u, v which lie in line correspond to three values of t, u, v which satisfy the given equation.

EXAMPLE (Fig. 23). Let $t = (uv)/(u + v)$, which may be written in the form $t/u + t/v = 1$. Here $U = u$, $V = v$, $F_1(t) = t$, $F_2(t) = t$.

NOTE. If $m = \infty$ and $n = \infty$, values of u and v which give large values of U and V cannot be shown within the limits of the paper. In such cases the chart may be supplemented by a second chart, made according to Method 3, above.

Method 5. Given, an equation which can conveniently be thrown into the form

$$F_2(t) = V \cdot F_1(t) + U,$$

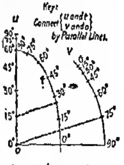
where, for the given range of values of t, the largest variation in $F_1(t)$ is less than a certain number m, and the largest variation in $F_2(t)$ is less than a certain number n.

Draw a pair of temporary x,y axes, and, having chosen a unit for x equal to about $(1/m)$th of the width of the paper and a unit for y equal to about $(1/n)$th of the height, plot the points (x,y) given by

$$x = F_1(t), \quad y = F_2(t),$$

labeling each point of the curve with the value of t to which it corresponds Connect these points by a smooth curve, which forms the t-scale. Next using the same unit for y as above, plot along the y-axis the values of U labeling each point with the corresponding value of u. This gives the u-scale. Finally, with the origin as center, and any convenient radius, draw a circle cutting the x-axis in A. Along this circular arc, starting from A in the counterclockwise direction, lay off the angles whose slopes are equal to V, labeling each point of the arc with the value of v to which it corresponds. This gives the v-scale, which in this case, however, plays a peculiar rôle, since, in using this form of chart, two straight lines are required instead of one. Thus:

In order to determine whether three values, t, u, v, satisfy the given equation, lay one straight line through the points t and u, and another straight line through the point v and the origin; if these lines are parallel, the three values of t, u, v satisfy the equation. It will be noticed that the function of the v-scale here is to measure, in a certain sense, the slope of the line joining t and u. A chart of this type may be called "an alignment chart with a sliding scale for one of the variables."



$\sin u = \sin 60° \sin t - \cos 60° \cos t \cos v$

FIG. 24.

EXAMPLE. Let $\sin u = \sin 60° \sin t - \cos 60° \cos t \cos v$ (Fig. 24), which may be put in the form

$$(\sin 60° \sin t) = \cos v \,(\cos 60° \cos t) + \sin u.$$

Here $F_1(t) = \cos 60° \cos t$, $F_2(t) = \sin 60° \sin t$, $U = \sin u$, $V = \cos v$.

Alignment Charts for Four Variables. The extension of methods 3, 4, and 5 to the case of four variables, say r, s, u, v, consists essentially in replacing the t-scale of the earlier diagram by a network of two scales, one for r and one for s. The point where a curve $r = r_1$ and a curve $s = s_1$ intersect may be spoken of as the point (r_1,s_1). In the following equations, U denotes as before any function of u alone, V any function of v alone; while $F_1(r,s)$ and $F_2(r,s)$ represent any functions of r and s.

Method 3a. Given, an equation of the form

$$U \cdot F_1(r,s) + V \cdot F_2(r,s) = 1.$$

MECHANICS OF RIGID BODIES

BY

H. W. HAYWARD

(Revised by J. P. Den Hartog and A. Haertlein)

KINEMATICS

Motion in a Straight Line—Rectilinear Motion

The position of a moving point at any instant may be stated by giving its distance and direction from some fixed point in its path which is taken as an origin. This distance s can be taken as a function of the time t, giving the equation of position $s = f(t)$.

Velocity. The velocity v of a moving point is the rate at which the distance s changes with respect to the time t, and may be uniform or varying.

$$v = ds/dt; \qquad s = \int v dt.$$

A space-time curve offers a convenient means for the study of the motion of a point. **The slope of the curve** at any point will represent the **velocity** at that time. In Fig. 1(*a*) the slope is constant, as the graph is a straight line; the velocity is therefore uniform. In Fig. 1(*b*) the slope of the curve varies from point to point, so the velocity must vary also. At p and q the slope is zero, therefore the velocity of the point at the corresponding times must also be zero.

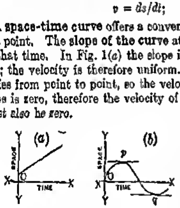


FIG. 1.

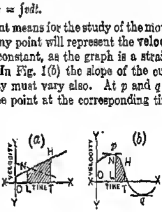

FIG. 2.

The acceleration a of a moving point is the rate at which its velocity v changes with respect to the time t, and may be uniform or varying, positive or negative.

For rectilinear motion, $a = dv/dt = d^2s/dt^2$; $s = \int\int a dt^2 = \int v dt$.

A velocity-time curve *offers a convenient means for the study of acceleration.* **The slope of the curve** at any point will represent the **acceleration** at that time. In Fig. 2(*a*) the slope is constant, so the acceleration must be constant. In the case represented by the full line, the acceleration is positive, so the velocity is increasing. The dotted line shows a negative acceleration and therefore a decreasing velocity. In Fig. 2(*b*) the slope of the curve varies from point to point, so the acceleration must also vary. At p and q the slope is zero, therefore the acceleration of the point at the corresponding times must also be zero and the velocity uniform. The area under the velocity-time curve between any two ordinates such as NL and HT will represent the distance moved in time interval LT. In the case of the uniformly accelerated motion shown by the full line in Fig. 2(*a*), the area $LNHT$ is $\frac{1}{2}(NL + HT) \times (OT - OL)$ = mean velocity multiplied by the time interval = space passed over during this time interval. In Fig. 2(*b*) the mean velocity can be obtained

along the y-axis, and the v-scale along a circular arc, precisely as in Method 5. Then any three points, (r,s), u, and v, which are so related that the line through (r,s) and u is parallel to the line joining v with the origin, will correspond to values of r, s, u, v which satisfy the given equation.

EXAMPLE for Method 5a (Fig. 27). Let $\cot v = \cot r \cos s + \csc r \sin s \cot u$, which may be written $(\cos r \cot s) = \cot v (\sin r \csc s) - \cot u$. Here $U = -\cot u$, $V = \cot v$, $F_1(r,s) = \sin r \csc s$, $F_2(r,s) = \cos r \cot s$, whence $\frac{x^2}{\csc^2 s} + \frac{y^2}{\cot^2 s} = 1$, $\frac{x^2}{\sin^2 r} - \frac{y^2}{\cos^2 r} = 1$, so that the s-curves are ellipses and the r-curves hyperbolas.

Parallel Charts, or Proportional Charts, for Four Variables. In the following methods of representation there are four scales, one for each of the four variables, and the method of using the diagram consists in connecting two pairs of points by parallel lines.

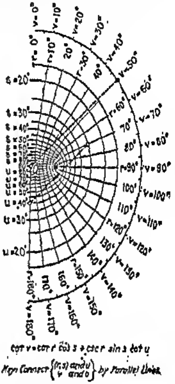

FIG. 27.

Method A. Given, an equation of the form

$$R - S = U - V$$

where R, S, U, V are any functions of the variables r, s, u, v, respectively. [It will be noted that any proportion $R/S = U/V$ can at once be thrown into this form by taking the logarithm of both sides.]

In Fig. 28, draw four vertical axes, y_1, y_2, y'_1, y'_2, such that the distance between y_1 and y'_1 (which may be zero) is equal to the distance between y_2 and y'_2, and so that the four zero points lie in line. Along these axes, using the same unit for all, plot the points given by $y_1 = R$, $y'_1 = S$, $y_2 = U$, $y'_2 = V$, and label each point with the value of r, s, u, or v to which it corresponds. (The letters y_1, y_2, y'_1, y'_2 are temporary, and should not appear on the diagram.) Then if the line joining two points r and u is parallel to the line joining two points s and v, the four values of r, s, u, v will satisfy the given equation. In this and the following methods, a parallel ruler, or a pair of draftsman's triangles, will be useful in reading the chart. A "key" stating which points are to be joined with which, should be clearly given on the diagram.

EXAMPLE (Fig. 28). Let $32.2\, vr = us^2$, or $\log r - 2 \log s = \log u - \log (32.2\, v)$. Here $R = \log r$, $S = 2 \log s$, $U = \log u$, $V = \log (32.2\, v)$.

Method B. Given, an equation of the form

$$\frac{R}{S} = \frac{U}{V}$$

In Fig. 29, draw a pair of axes, x,y, and parallel to them (or coinciding with them) a second pair of axes, x_1,y_1. Using any convenient horizontal unit, plot along x and x_1 the points given by $x = R$, $x_1 = U$, and using any convenient vertical unit, plot along y and y_1 the points given by $y = S$, $y_1 = V$. Label each point with the value of r, s, u, v, to which it corresponds. (The letters x, y, x_1, y_1 should not appear on the diagram.) Then if the line joining two points r and s is parallel to the line joining two points u and v, the four values r, s, u, v will satisfy the given equation.

moves about O its projection moves from O to Y, back to O, then to Y' and back to O again. This cycle of motion may be repeated indefinitely. If ωt is the variable angle XOp, the displacement s of n from O is $r \sin \omega t$, where $r = Op$. Velocity $v = ds/dt$, $\therefore v = \omega r \cos \omega t$. Acceleration $a = dv/dt$, $\therefore a = -\omega^2 r \sin \omega t = -\omega^2 s$. These equations assume that Op starts from position OX. If there is a lead angle $XOp' = B$, or a negative angle known as a lag, the expression will become $s = r \sin (\omega t + B)$, $v = \omega r \cos (\omega t + B)$, $a = -\omega^2 r \sin (\omega t + B) = -\omega^2 s$. When ωt has increased by 2π, *i.e.*, after the time $t = 2\pi/\omega$ has elapsed, s, v, and a regain their original values. t is called the **period of the motion**. The angle $(\omega t + B)$ is the **phase angle.**

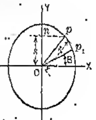

Fig. 5.

Composition and Resolution of Velocities

A velocity can be represented by a **vector**, which is a straight line having an arrow representing the direction of the motion and a length representing its magnitude.

Resultant. A velocity is said to be the resultant of two other velocities when it is represented by a vector that is the geometric sum of the vectors representing the other two velocities. This is the **parallelogram of motion.** In Fig. 6, v_r is the resultant of v_1 and v_2 and is represented by the diagonal of a parallelogram of which v_1 and v_2 are the sides; or it is the third side of a triangle of which v_1 and v_2 are the other two sides.

Fig. 6.

Polygon of Motion. The parallelogram of motion may be extended to the polygon of motion. Let v_1, v_2, v_3, v_4 [Fig. 7(a)] show the directions of four velocities imparted in the same plane to point O. If the lines v_1, v_2, v_3, v_4 [Fig. 7(b)] are drawn parallel to and proportional to the velocities imparted to point O, v_r will represent the resultant velocity imparted to O. It will make no difference in what order the velocities are taken in constructing the motion polygon. As long as the arrows showing the direction of the motion follow each other in order about the polygon, the resultant velocity of the point will be represented in magnitude by the closing side of the polygon, but opposite in direction.

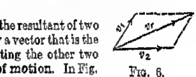

Fig. 7.

Resolution of Velocities. Velocities may be resolved into component velocities in the same plane, as shown by Fig. 8. Let the velocity of point O be v_r. In Fig. 8(a) this velocity is resolved into two components in the same plane as v_r and at right angles to each other.

$$v_r = \sqrt{(v_1)^2 + (v_2)^2}$$

In Fig. 8(b) the components are in same plane as v_r, but are not at right angles to each other. In this case,

$$v_r = \sqrt{(v_1)^2 + (v_2)^2 + 2v_1v_2 \cos B}$$

Fig. 8.

Multiplication of vectors is of two kinds, as follows:

The **scalar product**, or dot product, of two vectors $\mathbf{a}$ and $\mathbf{b}$, denoted by $\mathbf{a}\cdot\mathbf{b}$—or sometimes by $S\mathbf{ab}$, or by $(\mathbf{ab})$ in round parentheses—is defined as the scalar quantity $ab \cos \theta$, where θ is the angle between $\mathbf{a}$ and $\mathbf{b}$.

EXAMPLE. If $\mathbf{F}$ is a force whose point of application moves along a vector distance $\mathbf{x}$, then $\mathbf{F}\cdot\mathbf{x}$ = *work* done by $\mathbf{F}$ during this displacement.

Peculiarities of scalar products: (1) Since $\mathbf{a}\cdot\mathbf{b}$ is not a vector, expressions like $(\mathbf{a}\cdot\mathbf{b})\cdot\mathbf{c}$ will not occur; (2) from $\mathbf{a}\cdot\mathbf{x} = \mathbf{a}\cdot\mathbf{y}$ we cannot infer that $\mathbf{x} = \mathbf{y}$, hence, quotients will not occur; (3) from $\mathbf{a}\cdot\mathbf{b} = 0$, it follows that $\mathbf{a}$ is perpendicular to $\mathbf{b}$ (unless $\mathbf{a}$ or $\mathbf{b}$ is zero).

On the other hand, scalar products are like ordinary products in the following respects: $\mathbf{a}\cdot\mathbf{b} = \mathbf{b}\cdot\mathbf{a}$, and $(\mathbf{a} + \mathbf{b})\cdot(\mathbf{c} + \mathbf{d}) = \mathbf{a}\cdot\mathbf{c} + \mathbf{a}\cdot\mathbf{d} + \mathbf{b}\cdot\mathbf{c} + \mathbf{b}\cdot\mathbf{d}$; also, $m(\mathbf{a}\cdot\mathbf{b}) = (m\mathbf{a}\cdot\mathbf{b}) = \mathbf{a}\cdot(m\mathbf{b})$, where m is any scalar.

The **vector product**, or cross product, of two vectors a nd $\mathbf{b}$, denoted by $\mathbf{a}\times\mathbf{b}$—or sometimes by $V\mathbf{ab}$, or by $[\mathbf{ab}]$ in square bracket is defined as the *vector* whose length is $ab \sin \theta$, where θ is the angle betwee and $\mathbf{b}$, and whose direction is perpendicular to the plane of $\mathbf{a}$ and $\mathbf{b}$ (in such a sense that a right-handed screw advancing along $\mathbf{a}\times\mathbf{b}$ would turn $\mathbf{a}$ toward $\mathbf{b}$).

EXAMPLE. If $\mathbf{F}$ is a force acting on a particle whose radius vector is $\mathbf{r}$, then $\mathbf{r}\times\mathbf{F}$ = the *torque* of $\mathbf{F}$ about the origin.

Peculiarities of vector products: (1) $\mathbf{a}\times\mathbf{b} = -\mathbf{b}\times\mathbf{a}$, so that the order of the factors is always important; (2) $\mathbf{a}\times\mathbf{a} = 0$; (3) it is not true that $\mathbf{a}\times(\mathbf{b}\times\mathbf{c}) = (\mathbf{a}\times\mathbf{b})\times\mathbf{c}$; (4) from $\mathbf{a}\times\mathbf{x} = \mathbf{a}\times\mathbf{y}$ it does not follow that $\mathbf{x} = \mathbf{y}$; hence, quotients will not occur; (5) from $\mathbf{a}\times\mathbf{b} = 0$, it follows that $\mathbf{a}$ and $\mathbf{b}$ are **parallel** (unless $\mathbf{a}$ or $\mathbf{b}$ is zero).

On the other hand, as in ordinary algebra

$$(\mathbf{a} + \mathbf{b})\times(\mathbf{c} + \mathbf{d}) = \mathbf{a}\times\mathbf{c} + \mathbf{a}\times\mathbf{d} + \mathbf{b}\times\mathbf{c} + \mathbf{b}\times\mathbf{d},$$

provided the order of factors in each product is preserved; also, $m(\mathbf{a}\times\mathbf{b}) = (m\mathbf{a})\times\mathbf{b} = \mathbf{a}\times(m\mathbf{b})$, where m is any scalar. Further laws are:

$$\mathbf{a}\cdot(\mathbf{b}\times\mathbf{c}) = \mathbf{b}\cdot(\mathbf{c}\times\mathbf{a}) = \mathbf{c}\cdot(\mathbf{a}\times\mathbf{b}); \text{ and } \mathbf{a}\times(\mathbf{b}\times\mathbf{c}) = (\mathbf{a}\cdot\mathbf{c})\mathbf{b} - (\mathbf{a}\cdot\mathbf{b})\mathbf{c}.$$

Vector Differentiation. If $\mathbf{r} = \mathbf{f}(t)$ gives a vector $\mathbf{r}$ as a function of a scalar t, then $d\mathbf{r}/dt = \lim\{[\mathbf{f}(t + \Delta t) - \mathbf{f}(t)]/\Delta t\}$ as Δt approaches zero.

$$d(\mathbf{a} + \mathbf{b}) = d\mathbf{a} + d\mathbf{b}, \quad d(m\mathbf{a}) = m(d\mathbf{a}) + (dm)\mathbf{a},$$

$$d(\mathbf{a}\cdot\mathbf{b}) = (d\mathbf{a})\cdot\mathbf{b} + \mathbf{a}\cdot(d\mathbf{b}), \quad d(\mathbf{a}\times\mathbf{b}) = (d\mathbf{a})\times\mathbf{b} + \mathbf{a}\times(d\mathbf{b}).$$

EXAMPLE. If $\mathbf{r} = \mathbf{f}(t)$ gives the position-vector of a moving particle as a function of the time t, then $d\mathbf{r}/dt$ = its vector velocity, $\mathbf{v}$, and $d\mathbf{v}/dt$ = its vector acceleration, $\mathbf{a}$. If $\mathbf{m}$ and $\mathbf{n}$ are unit vectors in the direction of the tangent and normal to the path at the time t, then $\mathbf{v} = v\mathbf{m}$, where $v = ds/dt$ = the (scalar) path-velocity, and $d\mathbf{m} = [(ds/R)]\mathbf{n}$, where R = the (scalar) radius of curvature of the path. Then

$$\mathbf{a} = \frac{d(v\mathbf{m})}{dt} = \frac{dv}{dt}\mathbf{m} + v\frac{d\mathbf{m}}{dt} = \frac{dv}{dt}\mathbf{m} + \frac{v^2}{R}\mathbf{n}.$$

Here dv/dt and v^2/R are the familiar expressions for the components of acceleration along the tangent and normal.

Motion of a Particle in a Circular Path. If a point moves in a circle of radius r, its angular velocity being ω, angular acceleration a_a, and linear velocity v, $v = \omega r$, $a_t = a_a r$, $a_n = v^2/r = r\omega^2$.

Uniform Rotary Motion. In the case of uniform rotary motion, equal circular paths are traveled in equal intervals of time. ∴ Angular acceleration $a_a = 0$ and $a_t = a_a r = 0$. $a_n = v^2/r$. The **angular velocity** is usually expressed in **radians per sec**, and when the number (N) of revolutions per min (rpm) is known, the angular velocity is $\omega = 2\pi N/60 = 0.10472N$; linear velocity $v = \omega r$.

Compositions of Motions

A point may have several motions imparted to it at the same time by different means, in which case its motion is the resultant of the different component motions. Each of these components, by what is known as the **principle of independence**, exerts its full influence. The polygon or parallelopiped of motion may be used for the composition of motions.

Many examples of **combined motion** occur, *e.g.*, velocity given by gravity to a body having a horizontal motion; combined rotation and rectilinear motion of a point on a rolling wheel; a point whose motion is governed by the action of two or more cams; the movement of persons or machinery on board trains or boats; movement of a projectile.

Relative Motions. In order that a motion shall be fully determined, it is necessary that the base to which it is referred be carefully stated. The majority of engineering problems assume the earth as the reference base.

Motion of Rigid Bodies

A body is said to be rigid when the distances between all of its particles are invariable. Theoretically, rigid bodies do not exist, but materials used in engineering are practically rigid under their working stresses.

Elementary Motion. If a body moves so that a straight line connecting any two of its particles remains fixed in direction, it is said to have a motion of **translation**. If the motion is indefinitely small—distance $= ds$ and time $= dt$—it may be considered to have **elementary translation**; $ds/dt =$ velocity of translation. The elementary translation is fully determined by a line drawn from any point in the rigid body, representing the velocity in magnitude and direction.

If a body moves so that all its particles describe circles whose planes are at right angles to a straight line XX which contains simultaneously the centers of all the circles, it is said to have a **rotary motion** about the axis XX. If the motion is indefinitely small—angle of rotation $= d\theta$ and time $= dt$—it is called **elementary rotation**. The path ds of a point distant r from the axis of rotation is $ds = r d\theta$, and $d\theta/dt =$ elementary angular velocity of rotation. Elementary rotation is completely determined by a straight line whose length is equal to ω drawn on the axis of rotation with an arrow so placed that when looking in the direction of the arrow rotation takes place in a plane at right angles to that line and in the direction of the hands of a clock.

The motion of a body in space is determined by the motion of three points of the body which do not lie in the same straight line. The **instantaneous axis** is the axis about which a body is revolving at a given instant. If a body is being translated at a given instant, the instantaneous axis is at an infinite distance.

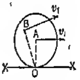

FIG. 15.

PHYSICAL MECHANICS

General Laws

Every particle of matter remains either at rest or moves uniformly in a straight line unless acted upon by some external influence. All variations of velocity, either in magnitude or direction, require the action of force.

Laws of Gravity. A body falling in a vacuum moves with a uniformly accelerated motion, the acceleration of the fall being the same for all bodies at the same place. Common values taken for this acceleration (usually designated as g) are 32.16 ft per sec per sec or 9.81 meters per sec per sec.

$g = 32.1721 - 0.08211 \cos 2a - 0.000003h$, where a is the latitude in degrees, and h the height in feet above sea level.

If a body is suspended by an elastic cord, the latter is elongated by the action of what is known as a force, in this case by the force of gravity. The suspended body is not only acted upon by gravity, but by a force exerted upon it by the cord, which imparts to it the same acceleration upward as gravity does downward, thereby maintaining the body at rest. The two forces are equal in magnitude.

Action is Equal to Reaction. The forces exerted by two bodies upon each other act in the same straight line are equal in magnitude and are opposite in direction.

Relations between Mass, Acceleration and Force. When acted upon by a constant unbalanced force, a body will move with a **uniformly accelerated motion. The accelerations produced in any body by different forces are proportional to the forces,** so that $a_1/p_1 = a_n/p_n$ = constant = $1/m$, where p_1, p_n are the forces applied and a_1, a_n are the resulting accelerations. The constant ratio m is known as the mass of the body.

Fundamental Equation: Force = mass × acceleration.

Mass $= w/g$, where w = weight and g = falling acceleration due to gravity.

$$F = (w/g)a = ma = mdv/dt = md^2s/dt^2.$$

In the case of two bodies at the same place, $w_1 = m_1g$, $w_2 = m_2g$ and $m_1/m_2 = w_1/w_2$; *i.e.*, **the masses of the two bodies are proportional to their weights.**

Example. If an unbalanced force of 5 lb acts upon a body weighing 10 lb, what will be the acceleration of the body? $5 = 10a/g$; $\therefore a = 5g/10 = g/2$.

Forces, like velocities and accelerations, are quantities in which **direction is a factor,** *i.e.*, their complete determination requires not only a statement of their magnitude, but also of their line of action and direction.

Law of the Conservation of Mass. The mass of a body remains unchanged by any ordinary physical or chemical change to which it may be subjected.

Technical Systems of Measurement

In absolute systems, see p. 72, the units of length, mass, and time are arbitrarily taken; all other units, including that of force, are derived.

from the equation of the curve by means of the calculus, or graphically by use of instruments.

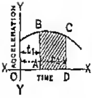

FIG. 3.

An acceleration-time curve (Fig. 3) may be constructed by plotting accelerations as ordinates, and times as abscissæ. The area under this curve between any two ordinates will represent the total increase in velocity during the time interval. The area *ABCD* represents the total increase in velocity between time t_1 and time t_2.

General Expressions Showing the Relations between Space, Time, Velocity and Acceleration, for Rectilinear Motion

Given $s = f(t)$; $v = ds/dt$, and $a = dv/dt = d^2s/dt^2$.

Given $v = f(t)$; $s = s_0 + \int_0^t v dt$, and $a = dv/dt$.

Given $v = f(s)$; $t = \int_{s_0}^{s} ds/v$, and $a = v dv/ds$.

Given $a = f(t)$; $v = v_0 + \int_0^t a dt$, and $s = s_0 + \int_0^t v dt$.

Given $a = f(s)$; $v = \sqrt{v_0^2 + 2\int_{s_0}^{s} a ds}$, and $t = \int_{s_0}^{s} ds/v$.

Given $a = f(v)$; $s = s_0 + \int_{v_0}^{v} \frac{v}{a} dv$, and $t = \int_{v_0}^{v} dv/a$

Special Motions

Uniform Motion. If the velocity is constant the acceleration must be zero, and the point has uniform motion. The space-time curve becomes a straight line inclined toward the time axis [Fig. 1(*a*)]. The velocity-time curve becomes a straight line parallel to the time axis. For this motion $a = 0$, $v =$ constant, and $s = s_0 + vt$.

Uniformly Accelerated or Retarded Motion. If the velocity is not uniform but the acceleration is constant, the point has uniformly accelerated motion; the acceleration may be either positive or negative. The space-time curve becomes a parabola and the velocity-time curve becomes a straight line inclined toward the time axis, Fig. 2(*a*). The acceleration-time curve becomes a straight line parallel to the time axis. For this motion $a =$ constant, $v = v_0 + at$, $s = s_0 + v_0t + \frac{1}{2}at^2$.

If the point starts from rest, $v_0 = 0$. Care should be taken concerning the sign + or − for acceleration.

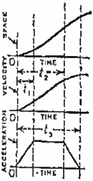

FIG. 4.

Example. Starting motion of a street car or hauling engine—see Fig. 4. During the period of time O to t_1, the acceleration increases from 0 to a maximum approximately in a straight line, the velocity-time curve is a parabola and the space-time curve one of the third degree. From t_1 to t_2 the acceleration is constant, the velocity increases uniformly, and the space-time curve is a parabola. From t_2 to t_3 the acceleration decreases from its maximum to 0 approximately in a straight line, and the space-time and velocity-time curves are like those from O to t_1. This concludes the start and a condition of equilibrium follows, with the acceleration zero, the velocity constant, and the space increasing uniformly.

Periodic Motion (Simple Harmonic Motion). If a point travels uniformly in a circle, the motion of its projection upon any diameter is a simple harmonic one. In Fig. 5, the line *Op* revolves about *O* with a uniform angular velocity ω; *n* is the projection of point *p* upon diameter *YY'*. As *p*

A force R may be resolved into two component forces intersecting anywhere on R and acting in the same plane as R, by the reverse of the operation shown by Figs. 16 and 17; and by repeating the operation with the components, R may be resolved into any number of component forces intersecting R at the same point and in the same plane.

Fig. 16.

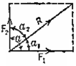

Fig. 17.

Resultant of Any Number of Forces Applied to a Rigid Body at the Same Point. Resolve each of the given forces F into components along three rectangular coordinate axes. If A, B and C are the angles made with XX, YY, and ZZ, respectively, by any force F, the components will be $F \cos A$ along XX, $F \cos B$ along YY, $F \cos C$ along ZZ; add the components of all the forces along each axis algebraically and obtain $\Sigma F \cos A = \Sigma X$ along XX, $\Sigma F \cos B = \Sigma Y$ along YY, and $\Sigma F \cos C = \Sigma Z$ along ZZ.

The resultant $R = \sqrt{(\Sigma X)^2 + (\Sigma Y)^2 + (\Sigma Z)^2}$. The angles made by the resultant with the three axes are A_r with XX, B_r with YY, C_r with ZZ, where

$$\cos A_r = \Sigma X/R, \qquad \cos B_r = \Sigma Y/R, \qquad \cos C_r = \Sigma Z/R.$$

The direction of the resultant can be determined by plotting the algebraic sums of the components.

If the forces are all in the same plane the components of each of the forces along one of the three axes (say, ZZ) will be 0, that is, angle $C_r = 90°$ and $R = \sqrt{(\Sigma X)^2 + (\Sigma Y)^2}$, $\cos A_r = \Sigma X/R$, and $\cos B_r = \Sigma Y/R$.

For equilibrium, it is necessary that $R = 0$; that is to say, ΣX, ΣY, and ΣZ must each be equal to zero.

General Law. In order that a number of forces acting at the same point shall be in equilibrium, the algebraic sum of their components along any *three* co-ordinate axes must each be equal to zero. When the forces all act in the same plane, the algebraic sum of their components along any *two* co-ordinate axes must each equal zero.

When the Forces Form a System in Equilibrium. Three unknown forces can be determined if the lines of action of the forces are *all* known and are in different planes. If the forces are all in the same plane, the lines of action being known, only *two* unknown forces can be determined. If the lines of action of the unknown forces are *not* known, only *one* unknown force can be determined in either case.

Couples and Moments

Couple. Two forces of equal magnitude, Fig. 18, which act in opposite and parallel directions form a couple. **A couple cannot be reduced to a single force.**

Displacement and Change of a Couple. The forces forming a couple may be moved about and their magnitude and direction changed, provided that they always remain parallel to each other, remain either in the original plane or one parallel to it, and provided that the product of one of the forces and the perpendicular distance between the two is constant and the direction of rotation remains the same.

Moment of a Couple. The moment of a couple is the product of the magnitude of one of the forces and the perpendicular distance between the lines of action of the forces. Fa = moment of couple; a = arm of couple.

If the components v_1 and v_2 and angle B are known, the direction of v_r can be determined. $\sin bOc = (v_1/v_r)\sin B$. $\sin cOa = (v_2/v_r)\sin B$. Where v_1 and v_2 are at right angles to each other, $\sin B = 1$.

Composition and Resolution of Accelerations. Accelerations may be combined and resolved in the same manner as velocities, but in this case the lines or vectors represent accelerations instead of velocities. Velocities and accelerations may be resolved into components *not* in the same plane by what is known as the **parallelopiped of motion.** In this case the **resultant of three motions not in the same plane** is the diagonal of a parallelopiped whose sides are lines whose length and direction represent the motions. See Fig. 9. Oa, Oc and Ob represent three velocities or accelerations; then Od represents the resultant velocity or acceleration. When the velocities or accelerations are at right angles to each other, the angles that the resultant Od makes with these axes are A, B and C, respectively. Then $\cos A = Oa/Od$, $\cos B = Ob/Od$, $\cos C = Oc/Od$, and

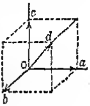

FIG. 9.

$$Od = \sqrt{Oa^2 + Ob^2 + Oc^2}.$$

Curvilinear Motion

The linear velocity $v = ds/dt$ is the same as for rectilinear motion, and its direction is tangent to the path of the point. In Fig. 10(a), let $p_1p_2p_3$ be the path of a moving point, and v_1, v_2, v_3 represent its velocity at points p_1, p_2, p_3, respectively. If O be taken as a pole [Fig. 10(b)] and vectors v_1, v_2, v_3 representing the velocities of the point at p_1, p_2, and p_3 be drawn, the curve connecting the terminal points of these vectors is known as the **hodograph** of the motion. This velocity diagram is applicable only to motions all in the same plane.

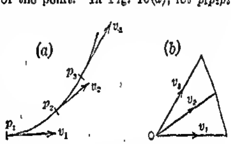

FIG. 10.

Acceleration. Tangents to the curve, Fig. 10(b), indicate the directions of the **momentary accelerations.** The direction of the tangents does not, as a rule, coincide with the direction of the velocities as represented by tangents to the path. If the acceleration a at some point in the path is resolved by means of a parallelogram into components tangent and normal to the path, the normal acceleration $a_n = v^2/r$, where r = radius of curvature of the path at the point in question, and the tangential acceleration $a_t = dv/dt$, where v = velocity tangent to the path at the same point. $a = \sqrt{a_n^2 + a_t^2}$. The normal acceleration is constantly directed toward the center of the path.

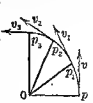

FIG. 11.

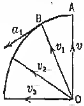

FIG. 12.

Example. Find the acceleration of a point moving in a circle with uniform velocity. In Fig. 11, p, p_1, p_2, p_3 is the circular path of a point. v, v_1, v_2, v_3 represent the uniform velocities at p, p_1, p_2, p_3. Construct the hodograph of the motion, as in Fig. 12. At point p_1 the acceleration is in the direction of the tangent to the hodograph at B, shown by line a_1. Let $pp_1 = s$, $AB = s_1$ and $Op = r$; then $s/r = s_1/v$. $\therefore s_1 = sv/r$. $ds_1/dt = (ds/dt)(v/r) = v^2/r$ and as $ds_1/dt = a_n$, $a_n = v^2/r$ and is in a direction toward the center of the circle, $a_t = 0$.

left of it (shown dotted), making the moment of the resultant about any point on F positive.

To effect a parallel displacement of a single force F over a distance a, a couple whose moment is Fa must be added to the system. The sense of the couple will depend upon which way it is desired to displace force F.

The moment of a force with respect to a point is the product of the force F and the perpendicular distance from the point to the line of action of the force.

The Moment of a Force with Respect to a Straight Line. If the force is resolved into components parallel and perpendicular to the given line, the moment of the force with respect to the line is the product of the magnitude of the perpendicular component and the distance from its line of action to the given line.

Forces with Different Points of Application

Composition of Forces. If each force F is resolved into components parallel to three rectangular coordinate axes XX, YY and ZZ, the magnitude of the resultant is $R = \sqrt{(\Sigma X)^2 + (\Sigma Y)^2 + (\Sigma Z)^2}$, and its line of action makes angles A_r, B_r and C_r with axes XX, YY and ZZ, where $\cos A_r = \Sigma X/R$, $\cos B_r = \Sigma Y/R$, and $\cos C_r = \Sigma Z/R$; and there are three couples which may be combined by their moment vectors into a single resultant couple having the moment $M_r = \sqrt{(M_x)^2 + (M_y)^2 + (M_z)^2}$, whose moment vector makes angles of A_m, B_m and C_m with axes XX, YY and ZZ, such that $\cos A_m = M_x/M_r$, $\cos B_m = M_y/M_r$, and $\cos C_m = M_z/M_r$. If this single resulting couple is in the same plane as the single resulting force at the origin or a plane parallel to it, the system may be reduced to a single force R acting at a distance from $R = M_r/R$. If the couple and force are not in the same or parallel planes, it is impossible to reduce the system to a single force. If $R = 0$, that is, if ΣX, ΣY and ΣZ all equal zero, the system will reduce to a single couple whose moment is M_r. If $M_r = 0$, that is, if M_x, M_y and M_z all equal zero, the resultant will be a single force R.

When the forces are all in the same plane, cosine of one of the angles A_r, B_r or $C_r = 0$, say, $C_r = 90°$. Then $R = \sqrt{(\Sigma X)^2 + (\Sigma Y)^2}$, $M_r = \sqrt{M_x^2 + M_y^2}$ and the final resultant is a force equal and parallel to R, acting at a distance from R equal to M_r/R.

A system of forces in the same plane can always be replaced by either a couple or a single force. If $R = 0$ and $M_r > 0$, the resultant is a couple. If $M_r = 0$ and $R > 0$, the resultant is a single force.

A rigid body is in equilibrium when acted upon by a system of forces whenever $R = 0$ and $M_r = 0$, *i.e.*, when the following six conditions hold true: $\Sigma X = 0$, $\Sigma Y = 0$, $\Sigma Z = 0$, $M_x = 0$, $M_y = 0$ and $M_z = 0$. When the system of forces is in the same plane, equilibrium prevails when the following three conditions hold true: $\Sigma X = 0$, $\Sigma Y = 0$, $\Sigma M = 0$.

Forces Applied to Support Rigid Bodies

The external forces in equilibrium acting upon a body may be statically determinate or indeterminate according to the number of unknown forces existing. When the forces are all in the same plane and act at a common point, two unknown forces may be determined if their lines of action are known, one if unknown.

Motion in a Plane

A plane motion is one in which all points of the moving body remain at constant distances from a fixed plane.

Angular Displacement. The angular displacement of any body moving in a plane is the angle described by any line drawn in the body parallel to the plane of the motion.

Angular velocity is the rate at which the angular displacement θ varies with respect to the time t. Angular velocity $\omega = d\theta/dt$.

Angular acceleration is the rate at which the angular velocity ω varies with respect to the time t. Angular acceleration $a_a = d\omega/dt = d^2\theta/dt^2$.

Instantaneous Axis. When the axis about which any body may be considered to rotate changes its position, any one position is known as an instantaneous axis, and the line through all positions of the instantaneous axis as the centrode.

When the motion of two points in the same plane of a rigid body having plane motion is known, the instantaneous axis for the body will be at the intersection of the lines drawn from each point and perpendicular to its line of motion. See Fig. 13, in which A and B are two points on the rod AB, v_1 and v_2 representing their velocities. O is the instantaneous axis for AB; $\therefore$ point C will move as shown in a line perpendicular to OC.

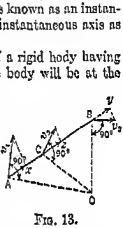

FIG. 13.

Linear velocities of points in a body rotating about an instantaneous axis are proportional to their distances from this axis. In Fig. 13, $v_1:v_2:v_3 = AO:OB:OC$. If the motions of A and B were parallel, the lines OA and OB would also be parallel and there would be no instantaneous axis. The motion of the rod would be translation, and all points would be moving with the same velocity in parallel straight lines.

If a body has plane motion, the components of the velocities of any two points in the body along the straight line joining them must be equal. Ax must be equal to By and Cz in Fig. 13.

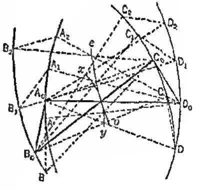

FIG. 14.

Centrode. If the path of the instantaneous center be plotted, the centrode for the motion of the body is obtained. See Fig. 14. Consider A_0B_0 to be fixed and let C_0D_0 rotate about it. Its motion being determined by the links AD and BC, the path of the instantaneous center for CD can be plotted as the curve xy. CD can be considered to be fixed and the centrode for AB found at eo. If the bars AB and CD are fixed to these centrodes and they are rolled upon each other, the relative motion of the two bars A_0B_0 and C_0D_0 will be the same as if they were connected by the links AD and BC. This principle is made use of in the design of **elliptic gears for quick-return motions.** If a wheel rolls along a track, the centrode is the surface of the track.

The angular velocity of a body at any time can be found by dividing the linear velocity of any point by the distance of the point from the instantaneous

on the member or by the member at these two points must be along a line connecting the pins.

If the external forces acting upon a rigid body in equilibrium are all in the same plane, the equations $\Sigma X = 0$, $\Sigma Y = 0$, and $\Sigma M = 0$ must be satisfied. When trusses, frames and other structures are under discussion, these equations are usually used as $\Sigma V = 0$, $\Sigma H = 0$, $\Sigma M = 0$, where V and H represent *vertical* and *horizontal* components, respectively.

The **supports** are said to be **determinate statically** when the laws of equilibrium are sufficient for their determination. When the conditions are not sufficient for the determination of the supports or other forces, the structure is said to be **statically indeterminate**; the unknown forces can then be determined from considerations involving the deformation of the *material*.

When several bodies are so connected to one another as to make up a rigid structure, the forces at the points of connection must be considered as internal forces and are not taken into consideration in the determination of the supporting forces for the structure as a whole.

The distortion of any practically rigid structure under its working loads is so small as to be negligible when determining supporting forces. When the forces acting at the different joints in a built-up structure cannot be determined by dividing the structure up into parts, the structure is said to be **statically indeterminate internally.** A structure may be statically *indeterminate internally and still be statically determinate externally.*

Fundamental Problems in Graphical Statics

A force may be represented by a straight line in a determined position, and its magnitude by the length of the straight line. The direction in which it acts may be indicated by an arrow.

FIG. 25.

Polygon of Forces. The parallelogram of two forces intersecting each other (see Fig. 8) leads directly to the graphic composition by means of the triangle of forces. In Fig. 25, R is called the **closing side**, and represents the resultant of the forces F_1 and F_2 in magnitude and direction. Its position is given by the point of application O. By means of repeated use of the triangle of forces and by omitting the closing sides of the individual triangles, *the magnitude and direction of the resultant R of any number of forces in the same plane and intersecting at a single point can be found.* In Fig. 26 the lines representing the forces start from point O, and in the force polygon, Fig. 27, they are joined in any order, the arrows showing their directions following around the polygon in the same direction. The magnitude of the resultant at the point of application of the forces is represented by the *closing side R* of the force polygon; its direction, as shown by the arrow, is counter to that in the other sides of the polygon.

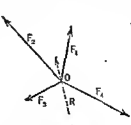

FIG. 26.

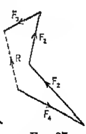

FIG. 27.

If the forces are in equilibrium, R must equal zero, *i.e.*, the force polygon must close.

If in a closed polygon one of the forces is reversed in direction, this force becomes the resultant of all the others.

In **gravitational systems**, the unit of length, force, and time are arbitrarily taken, the other units, including that of mass, being derived. The force unit is defined as the weight of a certain piece of metal, or of a prescribed volume of water, and thus this force unit depends on g and varies slightly with altitude and location.

STATICS OF RIGID BODIES

General Considerations

If the forces acting on a rigid body do not produce any acceleration, they must neutralize each other, that is, form a **system of forces in equilibrium.** Equilibrium is said to be **stable** when the body with the forces acting upon it returns to its original position after being displaced a very small amount from that position; **unstable** when the body tends to move still further from its original position than the very small displacement; and **neutral** when the forces retain their equilibrium when the body is in its new position.

External and Internal Forces. The forces by which the individual particles of a body act on each other are known as internal forces. All other forces are called external forces. If a body is supported by other bodies while subject to the action of forces, deformations and forces will be produced at the points of support or contact and these internal forces will be distributed throughout the body until equilibrium exists and the body is said to be in a state of tension, compression or shear. The forces exerted by the body on the supports are known as **reactions.** They are equal in magnitude and opposite in direction to the forces with which the supports act on the body, known as **supporting forces.** The supporting forces are external forces applied to the body.

In considering a body at a definite section, it will be found that all the internal forces act in pairs, the two forces being equal and opposite. The external forces act singly.

General Law. When a body is at rest, the forces acting externally to it must form an equilibrium system. This law will hold for any part of the body, in which case the forces acting at any section of the body become external forces when the part on either side of the section is considered alone. In the case of a rigid body, any two forces of the same magnitude but acting in opposite directions in any straight line, may be added or removed without change in the action of the forces acting on the body, providing the strength of the body is not affected.

Composition, Resolution and Equilibrium of Forces

(For graphical methods, see p. 202)

The **resultant** of several forces acting at a point is a force which will produce the same effect as all the individual forces acting together.

Forces Acting on a Body at the Same Point. The resultant R of two forces F_1 and F_2 applied to a rigid body at the same point is represented in magnitude and direction by the diagonal of the parallelogram formed by F_1 and F_2. See Figs. 16 and 17.

$$R = \sqrt{F_1^2 + F_2^2 + 2F_1F_2\cos a};\ \sin a_1 = (F_2 \sin a)/R;\ \sin a_2 = (F_1 \sin a)/R$$

When $a = 90$ deg, $R = \sqrt{F_1^2 + F_2^2}$, $\sin a_1 = F_2/R$ and $\sin a_2 = F_1/R$;

$$\left.\begin{array}{l}\text{When } a = 0 \text{ deg, } R = F_1 + F_2 \\ \text{When } a = 180 \text{ deg, } R = F_1 - F_2\end{array}\right\} \text{ Forces act in same straight line.}$$

straight line A_0A_n parallel to OO_1. **This line is the polar axis** of both funicular polygons.

Let the starting point of the force polygon be taken as a pole; then the sides of the funicular polygon will always give the line of action of the resultants of all the forces preceding. The last side will coincide with the resultant of all the forces.

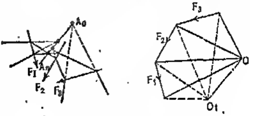

Fig. 31.

To determine the supporting forces for a rigid body when the external forces are all in the same plane and are statically determinate, see Fig. 32. *Let ab and bc be two forces acting* on beam which is supported at M by a roller and at N by a pin. Construct a force polygon, Fig. 32(b), using any convenient point O for a pole, and the funicular polygon shown in Fig. 32(a). This latter must start at N, as this is the only point on the line of action of the unknown force at N that is known. Draw the strings parallel to the corresponding rays of the force polygon and find that the last string intersects the line of action of the left-hand support at P. If the forces are in equilibrium, both force and funicular polygons must close. The closing side of the funicular polygon is PN. OD, Fig. 32(b), is drawn parallel to PN until it meets a line drawn from A parallel to the supporting force at M. The line CD closes the force polygon and gives the magnitude

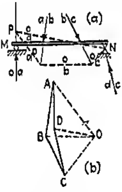

Fig. 32.

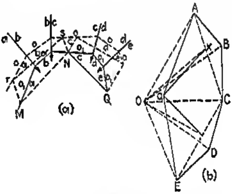

Fig. 33.

and direction of the supporting force at N. It is necessary that either the lines of action of both unknown supports, or the line of action of one and the point of application of the other, be known in order to use this construction.

To draw a **funicular polygon through three points,** see Fig. 33. Given the forces ab, bc, cd, and de, Fig. 33(a), let it be required to draw a funicular polygon so that any three given strings shall pass through any three given points, not on a straight line; for example, string oa through M, oc through N, and oe through Q. Construct a force polygon, Fig. 33(b), using O as a pole, and a corresponding funicular polygon, oa, ob, oc, od, oe Fig. 33(a). Consider the forces between points M and N; if they are to be balanced by two forces each parallel to their resultant and acting through M and N,

If the forces are measured in pounds and the distance a in feet, the **unit of rotation moment** is the foot-pound. If the force is measured in kilograms and the distance in meters, the unit is the meter-kilogram. In the cgs system the unit of rotation moment is 1 cm-dyne.

Rotation moments of couples acting in the same plane are considered to be positive or negative, according to whether they appear to rotate in the direction of the hands of a clock or in the reverse direction. The couple shown in Fig. 18 is positive. The magnitude, direction and sense of rotation of a couple are completely determined by its moment axis, or moment vector, which is a line drawn perpendicular to the plane in which the couple acts, with an arrow indicating the direction from which the couple will appear to have right-handed rotation; the length of the line represents the magnitude of the moment of the couple. See Fig. 19, in which AB represents the magnitude of the moment of the couple. Looking along the line in the direction of the arrow, the couple will have right-handed rotation in any plane perpendicular to the line.

Fig. 18.

Fig. 19.

Composition of Couples. Couples may be combined by adding their moment vectors geometrically, in accordance with the parallelogram rule, in the same manner in which forces are combined.

Couples lying in the same or parallel planes are added algebraically. Let $+40$, -60, and $+100$ ft-lb be the moments of three couples in the same or parallel planes; their resultant is a single couple lying in the same or in a parallel plane, whose moment is $\Sigma M = +40 - 60 + 100 = +80$ ft-lb.

If the polygon formed by the moment vectors of several couples closes itself, the couples form an equilibrium system. Two couples will balance each other when they lie in the same or parallel planes, and have the same moment in magnitude, but opposite in sign.

Combination of a Couple and a Single Force in the Same Plane. (See Fig. 20.) Given a force $F = 20$ lb acting as shown distant x from YY, and a couple whose moment is -60 ft-lb in the same or a parallel plane, to find the resultant. A couple may be changed to any other couple in the same or a parallel plane having the same moment and same sign. Let the couple consist of two forces of 20 lb each and let the arm be 3 ft. Place the couple in such a manner that one of its forces is opposed to the given force at p. This force of the couple and the given force being of the same magnitude and opposite in direction, will neutralize each other, leaving the other force of the couple acting at a distance of 3 ft from p and parallel and equal to the given force $F = 20$.

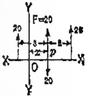

Fig. 20.

General Rule. The resultant of a couple and a single force lying in the same or parallel planes is a single force, equal in magnitude, in the same direction and parallel to the single force, and acting at a distance from the line of action of the single force equal to the moment of the couple divided by the single force. The moment of the resultant force about any point on the line of action of the given single force must be of the same sense as that of the couple, positive if the moment of the couple is positive, and negative if moment of couple is negative. If the moment of the couple in Fig. 20 had been $+60$ instead of -60, the resultant would have been a force of 20 lb acting in the same direction and parallel to F, but at a distance of 3 ft to the

Equilibrium. In order that the whole structure should be in equilibrium, it is necessary that the external forces (loads and supports) shall form a balanced system. Graphical and analytical methods are both of service.

Supporting Forces. When the supporting forces are to be determined, it is not necessary to pay any attention to the make-up of the structure under consideration so long as it is practically rigid; the loads may be taken as they occur, or the resultant of the loads may be used instead. When the stresses in the members of the structure are being determined, the loads *must* be distributed at the joints where they belong.

Method of Joints. When all the external forces have been determined, any joint at which there are not more than two unknown forces may be taken and these unknown forces determined by the methods of the stress polygon, resolution or moments. In Fig. 36, let O be the joint of a structure and F be the only known force; but let $O1$ and $O2$ be two members of the structure joined at O. Then the lines of action of the unknown forces are known and their magnitude may be determined (*a*) by a **stress polygon** which, for equilibrium, must close; (*b*) by resolution into H and V components, using the condition of equilibrium $\Sigma H = 0$, $\Sigma V = 0$; or (*c*) by moments, using any convenient point on the line of action of $O1$ or $O2$ and the condition of equilibrium $\Sigma M = 0$. No more than *two* unknown forces can be determined. In this manner, proceeding from joint to joint, the stresses in all the members of the truss can usually be determined if the structure is statically determinate internally.

FIG. 36.

The structure may be divided into two parts by passing a section through it cutting some of its members; one part may then be treated as a rigid body and the external forces acting upon it determined. Some of these forces will be the stresses in the members themselves. For example, let xx (Fig. 37) be a section taken through a truss loaded at P_1, P_2, and P_3, and supported on rollers at S. As the whole truss is in equilibrium, any part of it must be also, and consequently the part shown to the left of xx must be in equilibrium under the action of the forces acting externally to it. Three of these forces are the stresses in the members aa, bb, and bc, and are the unknown forces to be determined. They can be determined by applying the condition of equilibrium of forces acting in the same plane but not at the same point. $\Sigma H = 0$, $\Sigma V = 0$, $\Sigma M = 0$. The three unknown forces can be determined only if they are not parallel or do not pass through the same point; if, however, the forces are parallel or meet in a point, two unknown forces only can be determined. The conditions of equilibrium when using the funicular polygon construction are that both the funicular and force polygons must close. Sections may be passed through a structure cutting members in any convenient manner; as a rule, however, cutting not more than three members.

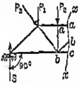

FIG. 37.

For the determination of stresses in framed structures, see p. 226.

Center of a Set of Parallel Forces; Center of Gravity

The center of a set of parallel forces is the point through which the resultant of the forces always passes, no matter how the forces are turned, providing that they always remain parallel and their points of application remain in the same relation to each other.

The resultant R of the two parallel forces F_1 and F_2 (Fig. 38) divides the line connecting the points of application A_1, A_2 into two segments a_1 and a_2

When the forces are all in the same plane and are parallel, two unknown forces may be determined if the lines of action are known, one if unknown.

When the forces are anywhere in the same plane, three unknown forces may be determined if their lines of action are known, if they are not parallel or do not pass through a common point; if the lines of action are unknown, only one unknown force can be determined.

If the forces all act at a common point but are in different planes, three unknown forces can be determined if the lines of action are known, one if unknown.

If the forces act in different planes but are parallel, three unknown forces can be determined if their lines of action are known, one if unknown.

The first step in the solution of problems in statics is the determination of the supporting forces. The following data are required for the complete knowledge of supporting forces: magnitude, direction, and point of application. According to the nature of the problem, none, one, or two of these quantities are known.

Fig. 21.

One Fixed Support. The point of application, direction, and magnitude of the load are known. See Fig. 21. As the body on which the forces act is in equilibrium, the supporting force P must be equal in magnitude and opposite in direction to the resultant of the loads L.

In the case of a **rolling surface,** the point of application of the support is obtained from the center of the connecting bolt A (Fig. 22), both the direction and magnitude being unknown. The point of application and line of action of the support at B are known, being determined by the rollers.

When three forces acting in the same plane on the same rigid body are in equilibrium, their lines of action must pass through the same point O. The load L is known in magnitude and direction. The line of action of the support at B is known on account of the rollers. The point of application of the support at A is known. The three forces are in equilibrium and are in the same plane, and therefore the lines of action must meet at the point O.

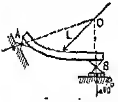

Fig. 22.

Fig. 23.

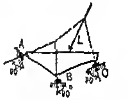

Fig. 24.

In the case of the rolling surfaces shown in Fig. 23, the direction of the support at A is known, the magnitude and point of application unknown. The line of action and point of application of the supporting force at B are known, its magnitude unknown. The lines of action of the three forces must meet in a point, and the supporting force at A must be perpendicular to the plane XX. In the case shown in Fig. 24, the directions and points of application of the supporting forces are known, and the magnitudes unknown. The lines of action of resultant of supports A and B, the support at C and load L must meet at a point. Resolve the resultant of supports at A and B into components at A and B, their direction being determined by the rollers.

If a member of a truss or frame in equilibrium is pinned at two points and loaded at these two points only, the line of action of the forces exerted

Trapezoid, Fig. 42. Cg lies on the line joining the middle points m and n of the parallel sides. The distances h_a and h_b are

$$h_a = h(a + 2b)/3(a + b); \quad h_b = h(2a + b)/3(a + b).$$

Draw $BE = a$ and $CF = b$; EF will then intersect mn at cg

Any Quadrilateral. The cg of any quadrilateral may be determined by the general rule for areas, or graphically by dividing it into two sets of triangles by means of the diagonals. Find the cg of each of the four triangles and connect the cg's of the triangles belonging to the same set. The intersection of these lines will be cg of area. Thus, in Fig. 43, O, O_1, O_2 and O_3 are respectively the centers of gravity of the triangles ABD, ABC, BDC, and ACD. The intersection of O_1O_3 with OO_2 gives cg.

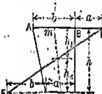

Fig. 42.

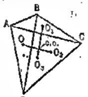

Fig. 43.

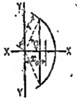

Fig. 44.

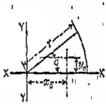

Fig. 45.

Segment of a Circle, Fig. 44: $x_0 = \frac{2}{3} r \sin^3 c/(\text{rad } c - \cos c \sin c)$. A segment may be considered to be a sector from which a triangle is subtracted, and the general rule applied.

Sector of a Circle, Fig. 45: $x_0 = \frac{2}{3} r \sin c/\text{rad } c$; $y_0 = \frac{4}{3} r \sin^2 \frac{1}{2}c/\text{rad } c$.

Semi-circle, $x_0 = \frac{4}{3} r/\pi = 0.4244r$; $y_0 = 0$.

Quadrant (90 deg sector): $x_0 = y_0 = \frac{4}{3} r/\pi = 0.4244r$.

Parabolic Half Segment, Fig. 46, Area ABO: $x_0 = \frac{3}{5} x_1$; $y_0 = \frac{3}{8} y_1$.

Parabolic Spandrel, Fig. 46, Area AOC: $x'_0 = \frac{3}{10} x_1$; $y'_0 = \frac{3}{4} y_1$.

Quadrant of an Ellipse, Fig. 47, Area OAB: $x_0 = \frac{4}{3}(a/\pi)$; $y_0 = \frac{4}{3}(b/\pi)$.

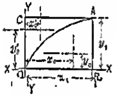

Fig. 46.

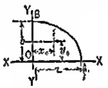

Fig. 47.

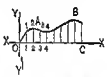

Fig. 48.

The center of gravity of a figure such as that shown in Fig. 48 may be determined as follows: Divide the area $OABC$ into a number of parts by lines drawn perpendicular to the axis XX, *e.g.*, 11, 22, 33, etc. These parts will be approximately either triangles, rectangles or trapezoids. The area of each division may be obtained by taking the product of its mean height and its base. The center of gravity of each area may be obtained as previously shown. The sum of the moments of all the areas about XX and YY, respectively, divided by the sum of the areas will give approximately the distances from the center of gravity of the whole area to the axes XX and YY. The greater the number of areas taken the more nearly exact the result.

Centers of Gravity of Solids

Prism or Cylinder with Parallel Bases. Cg lies in the center of the line connecting the centers of gravity of the bases.

If the forces do **not** all lie **in the same plane,** the diagram becomes a polygon in space. If the projections of the forces be drawn on any two planes, any horizontal and vertical, the closing lines of the projected polygons are the projections of the closing line of the force diagram in space.

Funicular Polygon

Composition of Forces in a Plane. In Fig. 28, to determine the resultant R of the forces ab, bc, cd, and de all in the same plane, construct the force polygon shown at (b). R will represent the magnitude and direction of the resultant force, and its location in (a) may be determined as follows: In Fig. 28(b) assume any convenient point O as a **pole,** draw the straight lines OA, OB, OC, OD and OE which are components of the given forces and in Fig. 28(a) draw the lines oa, ob, oc, od, oe parallel to the similarly lettered lines in Fig. 28(b). The location of oa in Fig. 28(a) is optional, so long as it intersects the line of action of ab. R must pass through the intersection of oa and oe and be parallel to AE in Fig. 28(b).

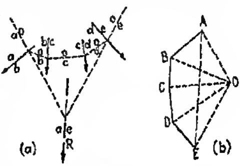

FIG. 28.

The figure $OABCDE$ is called the **polygon of forces** or **force polygon,** the lines OA, OB, OC, OD, OE in Fig. 28(b) are **rays,** and the series of lines oa, ob, oc, od, oe in Fig. 28(a) is called a **string polygon** or **funicular polygon,** oa, ob, oc, od, oe in (a) being known as **strings.** The following three cases may be met:

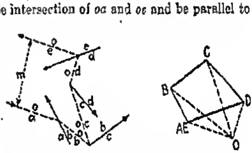

FIG. 29.

(a) The general case, where the starting point of the polygon of forces does not coincide with the terminal point. The resultant is a single force, as shown by Fig. 28. (b) The polygon of forces closes and the end strings of the funicular polygon are parallel. In this case (Fig. 29), the resultant is a couple whose moment is $OA \times m = OE \times m$. (c) The polygon of forces closes and the funicular polygon also closes, the result being **equilibrium.** See Fig. 30. The two coinciding terminal sides of the funicular polygon are called the **closing sides** or **strings.**

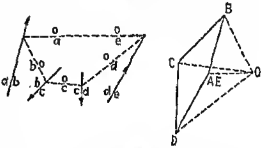

FIG. 30.

Let a polygon of forces and a funicular polygon be drawn for the system of forces shown in Fig. 31 with poles at both O and O_1. The intersections of the corresponding strings of the funicular polygons all lie in the same

The moment of inertia may be expressed in weight units ($I_w = \int y^2 dw$), in which case the moment of inertia in weight units, I_w, is equal to the moment of inertia in mass units, I, multiplied by g.

If $I = k^2 m$, the quantity k is called the **radius of gyration** or the **radius of inertia.**

If a body is considered to be composed of a number of parts, its moment of inertia about an axis is equal to the sum of the moments of inertia of the several parts about the same axis, or $I = I_1 + I_2 + I_3 + \cdots I_n$.

The moment of inertia of an area with respect to a given axis is the limit of the sum of the products of the elementary areas into which the area may be conceived to be divided and the square of their distance (y) from the axis in question. $I = \int y^2 dA = k^2 A$, where k = **radius of gyration.**

Formulae for moments of inertia and radii of gyration of various areas are given on pp. 457 to 460.

Relation between the Moments of Inertia of an Area and a Solid. The moment of inertia of a solid of elementary thickness about an axis is equal to the moment of inertia of the area of one face of the solid about the same axis multiplied by the mass per unit volume of the solid times the elementary thickness of the solid.

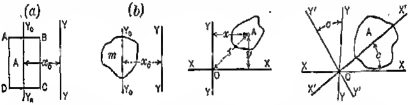

FIG. 52. FIG. 53. FIG. 54.

Moments of Inertia about Parallel Axes. The moment of inertia of an area or solid about any given axis is equal to the moment of inertia about a parallel axis through the center of gravity plus the square of the distance between the two axes times the area or mass.

In Fig. 52(a), the moment of inertia of the area $ABCD$ about axis YY is equal to I_0 (or the moment of inertia about Y_0Y_0 through the center of gravity of the area and parallel to YY) plus x_0^2A, where A = area of $ABCD$. In Fig. 52(b), the moment of inertia of the mass m about $YY = I_0 + x_0^2 m$. Y_0Y_0 passes through the cg of the mass and is parallel to YY.

Polar Moment of Inertia. The polar moment of inertia, Fig. 53, is taken about an axis perpendicular to the plane of the area. Referring to Fig. 53, if I_y and I_x be the moments of inertia of the area A about YY and XX, respectively, then the polar moment of inertia of area about $I_p = I_x + I_y$, or the polar moment of inertia is equal to the sum of the moments of inertia about any two axes at right angles to each other in the plane of the area and intersecting at the pole.

Moment of Deviation, or Product of Inertia. This quantity will be represented by I_{xy} and is $\iint xydydx$, where x and y are the co-ordinates of any elementary part into which the area may be conceived to be divided. I_{xy} may be positive or negative, depending upon the position of the area with respect to the co-ordinate axes XX and XY.

Relation between Moments of Inertia about Axes Inclined to Each Other. Referring to Fig. 54, let I_y and I_x be the moments of inertia of the

these two forces can be determined by drawing lines parallel to AC, Fig. 33(b), through M and N Fig. 33(a). The points where these lines are intersected by the funicular polygon are r and s, the closing side of a funicular polygon for these two forces is rs and the magnitude of the balancing forces can be determined as CX and XA, Fig. 33(b), by drawing from O a line parallel to rs and intersecting AC which is parallel to the forces at r and s. If the funicular polygon had passed through M and N, the same balancing forces for ab and bc parallel to AC must be found so that the locus of the poles of all the funicular polygons for ab and bc that will pass through M and N must lie on a line drawn from x and parallel to MN. In the same manner, the locus of the poles of all the funicular polygons for cd and de can be determined, and the intersection of these two loci will be the pole O_1 required.

Moment of Any System of Forces in a Plane. The resultant moment M of the forces ab, bc, cd (Fig. 34) with reference to point Q can be determined as follows: Fig. 34(b) is a force polygon for ab, bc, cd, using any convenient point O as a pole. Fig. 34(a) shows a corresponding funicular polygon. Through points Q and P of (a) draw lines parallel to the resultant of the forces R in (b); point P is the intersection of the end strings of the funicular polygon, and m and q are the points where the line drawn through point Q intersects the end strings. Consider the shaded triangles; the homologous sides are parallel, the triangles are therefore similar, and $mq/x = R/p$. $\therefore$ $(mq)p = Rx$; but Rx is the moment of the resultant of the forces with respect to Q: $\therefore$ $(mq)p$ must also be the same moment. mq is known as the **intercept** and p is known as the **pole distance.** In the case of parallel forces, the pole distance will be a constant; therefore, the moment at different points will vary as the intercept.

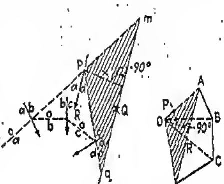

Fig. 34.

Resolution of Forces. Forces may be resolved into components in the same plane by means of the funicular polygon. See Fig. 35.

The funicular polygon is of great service in the solution of **stone arch and dam problems,** in determining the line of resistance at the joints. Bending moments and shearing forces for beams and other structures may also be determined graphically by its use.

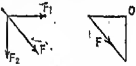

Fig. 35.

Determination of Stresses in Members of a Statically Determinate Plane Structure with Loads at Rest

It will be assumed that the loads are applied at the joints of the structure, *i.e.*, at the points where the different members are connected, and that the connections are pins with no friction. The stresses in the members must then be along lines connecting the pins, unless any member is loaded at more than two points by pin connections. If the members are straight, the forces exerted on them or by them must coincide with the axes of the members. In other words, there shall be no bending stresses in any of the members of the structure.

rectangle *edkg*, and triangles *mfg* and *hkl*, from which the rectangle *oprs* is to be subtracted. Referring to axis XX,

$I_{xx} = \pi 4^4/8$ for semi-circle *abc*; $= (2 \times 11^3)/3$ for rectangle *edkg*;
$= 2[(5 \times 3^3)/36 + 10^2(5 \times 3)/2]$ for the two triangles *mfg* and *hkl*.

From the sum of these there is to be subtracted $I_{xx}^1 = [(2 \times 3^3)/12 + 4^2(2 \times 3)]$ for the rectangle *oprs*.

If the moment of inertia of the whole area is required about an axis parallel to XX, but passing through the center of gravity of the whole area, $I_0 = I_{xx} - x_0^2 A$, where x_0 = distance from XX to center of gravity. The **moments of inertia of built-up sections** used in structural work may be found in the same manner, the moments of inertia of the different rolled sections being given in steel manufacturer's handbooks.

Moments of Inertia of Solids. For moments of inertia of solids about parallel axes, $I_x = I_0 + x_0^2 m$, see p. 210.

Moment of Inertia with Reference to Any Axis. Let a mass particle dm of a body have x, y and z as co-ordinates, XX, YY, and ZZ being the co-ordinate axes and O the origin. Let $X'X'$ be any axis passing through the origin and making angles of A, B and C with XX, YY and ZZ, respectively. The moment of inertia with respect to this axis then becomes =

$$I_{x'} = \cos^2 A\int(y^2 + z^2)dm + \cos^2 B\int(z^2 + x^2)dm + \cos^2 C\int(x^2 + y^2)dm$$
$$-2\cos B\cos C\int yz dm - 2\cos C\cos A\int zx dm - 2\cos A\cos B\int xy dm.$$

Let the moment of inertia about $XX = I_x = \int(y^2 + z^2)dm$, about $YY = I_y = \int(z^2 + x^2)dm$, and about $ZZ = I_z = \int(x^2 + y^2)dm$.

Let the products of inertia about the three co-ordinates axes be

$$I_{yz} = \int yz dm,\ I_{zx} = \int zx dm, \text{ and } I_{xy} = \int xy dm;$$

then the moment of inertia $I_{x'}$ becomes equal to

$$I_x\cos^2 A + I_y\cos^2 B + I_z\cos^2 C - 2I_{yz}\cos B\cos C - 2I_{zx}\cos C\cos A$$
$$-2I_{xy}\cos A\cos B$$

The moment of inertia of any solid may be considered to be made up of the sum or difference of the moments of inertia of simple solids of which the moments of inertia are known.

Moments of Inertia of Important Solids (Homogeneous)

$m = w/g$ = mass per unit of volume of the body.
$M = W/g$ = total mass of body.
r = radius. I = moment of inertia (mass units).
$I_w = I \times g$ = moment of inertia (weight units).

Solid circular cylinder about its axis:

$$I = \pi r^4 ma/2 = Mr^2/2. \quad (a = \text{length of axis of cylinder.})$$

Solid circular cylinder about an axis through the center of gravity and perpendicular to axis of cylinder: $I = M[r^2 + (a^2/3)]/4$.

Hollow circular cylinder about its axis:

$$I = \pi ma(r_1^4 - r_2^4)/2. \quad (r_1 \text{ and } r_2 = \text{outer and inner radii}; a = \text{length.})$$

Thin hollow circular cylinder about its axis: $I = Mr^2$.
Solid sphere about a diameter: $I = 8m\pi r^5/15 = 2Mr^2/5$
Thin hollow sphere about a diameter: $I = 2Mr_1^2/3$.
Thick hollow sphere about a diameter:

$$I = 8m\pi(r_1^5 - r_2^5)/15. \quad (r_1 \text{ and } r_2 \text{ are outer and inner radii.})$$

Rectangular prism about an axis through center of gravity and perpendicular to a face whose dimensions are a and b: $I = M(a^2 + b^2)/12$.

at the point S. $F_1a_1 = F_2a_2$. The point S is independent of the direction of the parallel forces, provided they always remain parallel and applied at A_1 and A_2. The point S, through which the resultant always passes, is called the center of the parallel forces F_1 and F_2.

The static moment of a line, surface or solid with respect to an axis is the length of the line, the area of the surface or the weight of the solid multiplied by the distance from the axis to the center of gravity of the line, surface or solid.

Fig. 38.

Centers of Gravity of Lines. To find the center of gravity of a line, divide it into an indefinitely large number of indefinitely short lengths, to be known as elementary divisions. Multiply the length of each elementary division by its perpendicular distance from some reference axis in a plane containing the line. When the line is all on one side of the axis, add these products (or moments, as they are usually designated), but when the line is on both sides of the axis, subtract the moments of the part on one side from the moments of the part on the other. Divide this sum or difference by the total length of the line, and the quotient will be the perpendicular distance from the axis to the center of gravity of the line and should be measured on the side of the axis that has the greater moment if the line is on both sides of the axis.

Centers of Gravity of Plane Areas. Proceed in the same manner as for lines, dividing the area into elementary areas. If the plane area has an axis of symmetry, the center of gravity lies on this axis.

Centers of Gravity of Technically Important Lines, Areas, and Solids

Centers of Gravity of Lines

Straight Line. The center of gravity is at its middle point.

Circular Arc AB, Fig. 39(a): $x_0 = r \sin c/\text{rad } c$; $y_0 = 2r \sin^2 \frac{1}{2}c/\text{rad } c$. (rad c = angle c measured in radians; see p. 44.)

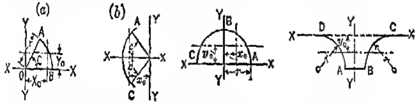

Fig. 39. Fig. 40. Fig. 41.

Circular Arc AC, Fig. 39(b): $x_0 = r \sin c/\text{rad } c$; $y_0 = 0$.

Quadrant, AB, Fig. 40: $x_0 = y_0 = 2r/\pi = 0.6366\ r$.

Semi-circumference, AC, Fig. 40: $y_0 = 2r/\pi = 0.6366r$; $x_0 = 0$.

Combination of Arcs and Straight Line, Fig. 41: AD and BC are two quadrants of radius r. $y_0 = \{(AB)r + 2[0.5\pi r(r - 0.6366r)]\} \div [AB + 2\ (0.5\pi r)]$.

Centers of Gravity of Plane Areas

Triangle. Center of gravity cg lies at the intersection of the lines joining the vertices with the mid-points of the sides, and at a distance from any side equal to one-third of the corresponding altitude.

Parallelogram. Cg lies at the point of intersection of the diagonals.

from XX to the center of gravity of MNP = area $M'N'P' \times d$/area MNP. Also, area $M''N''P'' \times d^2$ = moment of inertia of MNP about XX. The areas $M'N'P'$ and $M''N''P''$ can best be obtained by use of a planimeter.

DYNAMICS OF RIGID BODIES

Motion Under Unbalanced Forces

If a body is acted upon by a system of forces forming a balanced system, it will either remain at rest or move uniformly in a straight line. Only unbalanced forces change the motion of a body.

Uniformly accelerated or retarded motion requires the action of a constant unbalanced force. A common example of **uniformly accelerated motion** is the action of gravity on a falling body. If the action of gravity is wholly unresisted, the velocity v at the end of time t (in sec), starting from rest, will be $v = gt$, where g = acceleration due to gravity. If the body has an initial velocity v_0, $v = v_0 + gt$. An example of **uniformly retarded motion** is that of a body projected into the air vertically with a velocity v_0; its velocity after any time t will be $v = v_0 - gt$. If s = space passed through, $s = \frac{1}{2}gt^2$ for a falling body starting from rest, and $s = v_0t + \frac{1}{2}gt^2$ if starting with an initial velocity v_0. For a body projected vertically upward, $s = v_0t - \frac{1}{2}gt^2$.

General Formulas for the Motion of a Body Under the Action of a Constant Unbalanced Force

s = space in ft, a = acceleration in ft per sec per sec; v = velocity in ft per sec, v_0 = initial velocity in ft per sec, h = height in ft, F = force; m = mass, w = weight, g = acceleration due to gravity.

Initial velocity = 0:	Initial velocity = v_0:
$F = ma = (w/g)a.$	$F = ma = (w/g)a.$
$v = at.$	$v = v_0 + at.$
$s = \frac{1}{2}at^2 = \frac{1}{2}vt.$	$s = v_0t + \frac{1}{2}at^2 = \frac{1}{2}v_0t + \frac{1}{2}vt.$

$v = \sqrt{2as} = \sqrt{2gh}$ (falling freely from rest).

If a body is to be moved in a straight line by a force, the line of action of this force must pass through its center of gravity.

General Rule for the Solution of Problems When the Forces Are Constant in Magnitude and Direction. Resolve all the forces acting on the body into two components, one in the direction of the body's motion and one at right angles to it. Add the components in the direction of the body's motion algebraically and find the **unbalanced force**, if any exists.

Examples. (a) The body in Fig. 63 weighs 100 lb, is subjected to external forces F and F_1, and the coefficient of friction between the body and the inclined plane is 0.1. Required, the velocity of the body at the end of five (5) sec if it starts from rest.

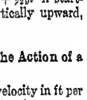

Fig. 63.

First, determine all of the forces acting externally to the body. These are F = 40 lb, F_1 = 80 lb, W = 100 lb, and the force with which the plane reacts upon the body. Resolve the forces into components along the plane and normal to it. The components along the plane are 32 lb and 60 lb acting down, 80 lb acting up, and that component of the plane's resistance which acts against motion. This component of the plane's resistance is the normal component of the pressure between the surfaces multiplied by 0.1, which is the coefficient of friction. The components normal to the plane are 24 lb acting away and 80 lb acting toward the plane. The normal pressure is 80 − 24 = 56 lb, and the friction is 56 × 0.1 = 5.6 lb. The unbalanced force acting on the body along the plane is

Oblique Frustum of a Right Circular Cylinder, Fig. 49. Let 1 2 3 4 be the plane of symmetry. The distance from the base to the cg is $\frac{1}{2}h + (r^2 \tan^2 c)/8h$, where c is the angle of inclination of the oblique section to the base. The distance of the cg from the axis of the cylinder is $r^2 \tan^2 c/4h$.

Fig. 49.

Pyramid or Cone. Cg lies in the line connecting the cg of base with the vertex and at a distance of one-fourth of the altitude above the base.

Truncated Pyramid. If h is the height of the truncated pyramid and A and B the areas of its bases, the distance of its cg from the surface of A is

$$h(A + 2\sqrt{AB} + 3B)/4(A + \sqrt{AB} + B).$$

Truncated Circular Cone. If h is the height of the frustum and R and r the radii of the bases, the distance from the surface of the base whose radius is R to the center of gravity is $h(R^2 + 2Rr + 3r^2)/4(R^2 + Rr + r^2)$.

Segment of a sphere, Fig. 50, volume ABC: $x_0 = 3(2r - h)^2/4(3r - h)$.

Hemisphere. $x_0 = 3r/8$.

Hollow Hemisphere. $x_0 = 3(R^4 - r^4)/8(R^3 - r^3)$, where R and r are respectively the outer and inner radii.

Sector of a sphere, Fig. 50, volume $OABCO$: $x'_0 = \frac{3}{8}(2r - h)$.

Ellipsoid, with semi-axes a, b and c. For each octant, distance from center of gravity to each of the bounding planes = $\frac{3}{8}$ × length of semi-axis perpendicular to the plane considered.

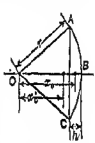

Fig. 50.

The formulas given for the determination of the centers of gravity of lines and areas can be used to determine the areas and volumes of surfaces and solids of revolution, respectively, by employing the theorems of Pappus, p. 111.

Determination of Center of Gravity of a Body by Experiment. The center of gravity may be determined by hanging the body up from different points and plumbing down; the point of intersection of the plumb lines will give the center of gravity. The cg may also be determined as shown in Fig. 51. The body is placed on knife edges which rest on platform scales. The sum of the weights registered on the two scales ($w_1 + w_2$) must equal the weight (w) of the body. Taking a moment axis at either end (say, O), $w_2A/w = x_0$ = distance from O to plane containing the center of gravity.

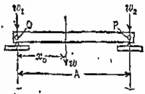

Fig. 51.

Graphical Determination of the Centers of Gravity of Plane Areas. See p. 213 and Fig. 62.

Moment of Inertia

The moment of inertia of a solid body with respect to a given axis is the limit of the sum of the products of the masses of each of the elementary particles into which the body may be conceived to be divided and the square of their distance from the given axis.

If $dm = dw/g$ represents the mass of an elementary particle and y its distance from an axis, the moment of inertia I of the body about this axis will be $I = \int y^2 dm = \int y^2 dw/g$.

Let ω be the angular velocity of point A. Consider that it starts from X' and moves to A in time t; then the angle $B = \omega t$. If $CA = r$, $X'P = r - CP = r - r \cos \omega t = s$. The velocity v of the point P will equal $ds/dt = \omega r \sin \omega t$, and the acceleration $a = dv/dt = -\omega^2 r \cos \omega t$. The unbalanced force acting on the body P at any time $= F = ma = m\omega^2 r \cos \omega t = (w/g)\omega^2 r \cos \omega t = m\omega^2 CP$, showing that the force varies as the distance of the body from the center of its path, being 0 at the center and $(w/g)\ \omega^2 r$ at the ends of the path. The velocity is 0 at the ends and a maximum at the middle, where $v = \omega r$.

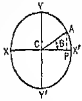

FIG. 66.

When a body is acted upon by varying forces, methods similar to those adopted for constant forces are used, but, in general, more simple solutions can be found by using the principles of work and energy.

Work and Energy

Work. When a body is displaced against resistance or accelerated, work must be done upon it. The work done by a constant force is the force F multiplied by the distance through which the force moves, or work $= Fs$. The work done by a force that varies $= \int Fds$ when the force F is expressed as a function of the space s. In the **work diagram**, Fig. 67, the ordinates are forces at different times and the abscissas are spaces passed over. The area under the curve represents the work done, which is equal to $\int Fds$.

Units of Work. When the force of 1 lb acts through the distance of 1 ft **1 ft-lb** of work is done. The **foot-ton** unit is sometimes used. In countries using the metric system the unit employed is the **meter-kilogram.**

Energy. A body is said to possess energy when it can do work. A body may possess this capacity through its **position** or **condition.** When a body is so held that it can do work, if released, it is said to possess energy of position or **potential energy.** When a body is moving with some velocity, it is said to possess energy of motion or **kinetic energy.** An example of potential energy is a body held suspended by a rope; the position of the body is such that if the rope be removed work can be done by the body.

Energy is expressed in the same units as work. The kinetic energy of a body is expressed by the formula $E = \frac{1}{2}mv^2 = \frac{1}{2}(w/g)v^2$.

If a force which varies acts through a space on a body of mass m, the work done is $\int_{s_1}^{s_2} Fds$, and if the work is all used in giving kinetic energy to the body it is equal to $\frac{1}{2}m(v_2^2 - v_1^2) =$ **change in kinetic energy,** where v_2 and v_1 are the velocities at distances s_2 and s_1 respectively. For the kinetic energy of rotation, see p. 220.

If a force which varies acts for a certain time on a body of mass m, the quantity $\int_{t_0}^{t_1} Fdt = m(v_1 - v_0)$, = the **change in momentum** of the body.

Certain problems in which the velocity of a body at any point in its straightline path when acted upon by varying forces is required, can be easily solved by the use of a **work diagram.**

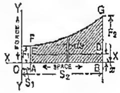

FIG. 67.

In Fig. 67, let a body weighing 100 lb start from rest at A and be acted upon by a force that varies in accordance with the diagram $AFGBA$. Let the resistance to motion be a constant force $= x$. Find the velocity of the body at point B. The area $AFGBA$ represents the work done upon the body and the area $AEDBA$ (= force x × distance AB) represents the work that

area A about YY and XX, respectively, I_y' and I_x' the moments about $Y'Y'$ and $X'X'$, and I_{xy} and I_{xy}' the products of inertia for XX and YY, and $X'X'$ and $Y'Y'$, respectively. Also, let c be the angle between the respective pairs of axes, as shown. Then,

$$I_y' = I_y \cos^2 c + I_x \sin^2 c + I_{xy} \sin 2c$$
$$I_x' = I_x \cos^2 c + I_y \sin^2 c - I_{xy} \sin 2c$$
$$I_{xy}' = \frac{(I_x - I_y)}{2} \sin 2c + I_{xy} \cos 2c$$

Principal Moments of Inertia. In every plane area, a given point being taken as the origin, there is at least one pair of rectangular axes in the plane of the area about one of which the moment of inertia is a maximum, and a minimum about the other. These moments of inertia are called the **principal moments of inertia**, and the axes about which they are taken are the **principal axes of inertia.** One of the conditions for principal moments of inertia is that the product of inertia I_{xy} shall equal zero. **Axes of symmetry** of an area are always principal axes of inertia.

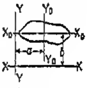

FIG. 55.

Relation between Products of Inertia for Parallel Axes. In Fig. 55, X_0X_0 and Y_0Y_0 pass through the center of gravity of the area parallel to the given axes XX and YY. If I_{xy} be the product of inertia for XX and YY, and $I_{x_0y_0}$ that for X_0X_0 and Y_0Y_0, then $I_{xy} = I_{x_0y_0} + abA$.

Ellipse of Inertia. In Fig. 56, let $I_y = \int x^2dA$ and $I_x = \int y^2dA$ be the moments of inertia about the principal axes XX and YY. The moment of inertia about axis $AA = I_y \sin^2 c + I_x \cos^2 c$, as $I_{xy} = 0$. The polar equation of an ellipse constructed on the semiaxes a and b will be $a^2 \sin^2 c + b^2 \cos^2 c = (a^2b^2)/r^2$, r being the radius vector of any point on the ellipse and c the angle that it makes with XX. Lay off $a = \sqrt{I_y}$ and $b = \sqrt{I_x}$; then the moment of inertia about $AA = (a^2b^2)/r^2 = I_xI_y/r^2$.

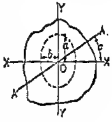

FIG. 56.

The moment of inertia of the area about any axis in the plane and passing through O will be inversely proportional to the square of the semi-diameter cut by that axis from an ellipse constructed with $a = \sqrt{I_y}$ and $b = \sqrt{I_x}$, a and b being the semi-major and semi-minor axes, respectively.

The following **conclusions** may be drawn: If the principal moments of inertia are equal, the ellipse of inertia becomes a circle and the moments of inertia about all axes in the plane and passing through O are the same. If the moments of inertia about more than two axes in the plane and passing through O are equal, the moments of inertia about all axes in the plane and passing through O are the same. There are two axes in the plane making equal and opposite angles with a principal axis and passing through O, about which the moments of inertia are equal.

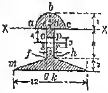

FIG. 57.

The moment of inertia of any area may be considered to be made up of the sum or difference of the known moments of inertia of simple figures. For example, the dimensioned figure shown in Fig. 57 represents the section of a rolled shape with hole *oprs*, and may be divided into the semi-circle *abc*,

the body to the connection is called a **centrifugal force.** The acceleration toward the axis necessary to keep a particle moving in a circle about that axis is v^2/r; therefore the force necessary is $ma = mv^2/r = wv^2/gr = w\pi^2N^2r/900g$, where N = rpm. This force is constantly directed toward the axis.

The centrifugal force of a solid body revolving about an axis is the same as if the whole mass of the body were concentrated at its center of gravity. Centrifugal force $= wv^2/gr = mv^2/r = w\omega^2r/g$, where w and m are the weight and mass of the whole body, r is the distance from the axis about which the body is rotating to the center of gravity of the body, ω the angular velocity of the body about the axis in radians, and v the linear velocity of the center of gravity of the body.

Examples (Uniform angular velocity). (1) In Fig. 69 a homogeneous rod of length l revolves about XX at a speed of N rpm: find the pressure on the axis XX due to centrifugal force (C. F.). As the whole body is deviated toward XX, the force necessary must be C. F. $= (w/g)(2\pi N/60)^2(l/2)$, w being the weight deviated, $2\pi N/60$ = the angular velocity and $l/2$ the distance from axis to center of gravity.

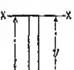

FIG. 69.

(2) Find the tension in the rod at aa, distant y from the axis. The force with which the length y of the rod acts on the length ab is the deviating force necessary to keep $aabba$ constantly accelerated toward the axis. This force $= \dfrac{w'}{g}\left(\dfrac{2\pi N}{60}\right)^2\left[y + \dfrac{(l-y)}{2}\right]$ w' being the weight of $aabba$, and $\left[y + \dfrac{(l-y)}{2}\right]$ being the distance from XX to the center of gravity of $aabba$.

(3) In Fig. 70 find the pressure on the axis YY and maximum tension due to centrifugal force. Determine the center of gravity of the body; let it be r_0 from the axis YY; then the pressure on the axis will be $(w/g)(2\pi N/60)^2r_0$. To determine the maximum tension due to centrifugal force, determine which part of the body on one side of the axis has the greater moment about the axis; the maximum tension will be on this side of the axis, and the pressure on the axis will be the difference between the tensions on the two sides.

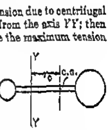

FIG. 70.

The tension in a belt, in lb per sq ft, due to centrifugal force is wv^2/g, where w = weight of material per cu ft, and v = velocity, fps. It should be noted that the *tension is independent of the diameter of the pulley* upon which the belt runs.

A body revolving about an axis passing through its center of gravity exerts no pressure on the axis due to centrifugal force.

Conical Pendulum. In the simple revolving pendulum shown in Fig. 71 a ball weighing w lb revolves about YY at a speed of N rpm; find the angle a. The forces acting upon the mass of the ball are the weight w and the tension T in the cord. As the ball stands out at a constant angle, the vertical component of T must equal w, leaving the horizontal component of T unbalanced. This unbalanced component is the deviating force necessary to keep the weight revolving about YY. This deviating force is the centripetal force.

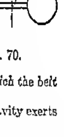

FIG. 71.

$T \sin a$ = C. F. and $T \cos a = w$, but C. F. $= w\omega^2r/g$; $\therefore$ $T \sin a = w\omega^2r/g$, $T = w\omega^2r/g \sin a$, and $\sin a = w\omega^2r/gT$; $r = l \sin a$, and $\omega = 2\pi N/60$. From these formulas the tension and angle can be found if N is known, or the tension and number of revolutions per minute can be determined if the angle is known. It should be noted that ω^2l must be greater than g.

Solid right circular cone about an axis through its apex and perpendicular to its axis:

$I = 3M[(r^2/4) + h^2]/5$. (h = altitude, of cone, r = radius of base.)

Solid right circular cone about its axis of revolution: $I = 3Mr^2/10$.

Ellipsoid with semi-axes a, b, and c: I about diameter $2c$ (z-axis) = $I = 4m\pi abc\,(a^2 + b^2)/15$.

[Equation of ellipsoid: $(x^2/a^2) + (y^2/b^2) + (z^2/c^2) = 1$.]

Ring with Circular Section, Fig. 58:

$I_{yy} = \frac{1}{4}m\pi^2Ra^2(4R^2 + 3a^2)$;

$I_{xx} = m\pi^2Ra^2[R^2 + (5a^2/4)]$.

Approximate Moments of Inertia of Solids. In order to determine the moment of inertia of a solid, it is necessary to know all its dimensions. In the case of a rod of mass M, Fig. 59, and length l, with shape and size of the cross-section unknown, making the approximation that the weight is all concentrated along the axis of the rod, the moment of inertia about YY will be $I_{yy} = \int_0^l (M/l)x^2dx = Ml^2/3$.

Fig. 58.

Fig. 59.

Fig. 60.

A thin plate may be treated in the same way (Fig. 60):

$$I_{yy} = \int_0^l (M/l)x^2dx$$

Here the mass of the plate is assumed as concentrated at its middle layer.

Thin Ring, or Cylinder (Fig. 61). Assume the mass, M, of the ring or cylinder to be concentrated at a distance r from O. The moment of inertia about an axis through O perpendicular to plane of ring or along axis of cylinder will be $I = Mr^2$; this will be greater than the exact moment of inertia, and r is sometimes taken as the distance from O to the center of gravity of the cross-section of the rim.

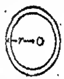

Fig. 61.

Fly-wheel Effect. The moment of inertia of a solid is often called fly-wheel effect in the solution of problems dealing with rotating bodies, and is usually expressed in lb-ft² (I_w).

Graphical Determination of the Centers of Gravity and Moments of Inertia of Plane Areas. Required, to find the center of gravity of the area MNP, Fig. 62, and its moment of inertia about any axis XX.

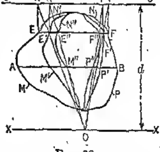

Fig. 62.

Draw any line SS parallel to XX and at a distance d from it. Draw a number of lines such as AB and EF across the figure parallel to XX. From E and F draw ER and FT perpendicular to SS. Select as a pole any point O on XX, preferably the point nearest the area, and draw OR and OT, cutting EF at E' and F'. If the same construction is repeated, using other lines parallel to XX, a number of points will be obtained, which, if connected by a smooth curve, will give the area $M'N'P'$. Project E' and F' on to SS by lines $E'R'$ and $F'T'$. Join R' and T' with O', obtaining E'' and F''; connect the points obtained using other lines parallel to XX and obtain an area $M''N''P''$. The area $M'N'P' \times d$ = moment of area MNP about the line XX, and the distance

Rotation of Solid Bodies about Axes

If a body rotates about an axis under the action of a constant force F, the relations between the angular acceleration a_c, the angular velocity ω, the angle moved through θ, and the kinetic energy of rotation E, are $Fl = a_c I$; $\omega = a_c t$, or $= \omega_0 + a_c t$; $\theta = \frac{1}{2}a_c t^2 = \frac{1}{2}\omega t$, or $= \omega_0 t + \frac{1}{2}a_c t^2$; $E = \omega_1^2 I/2$; where Fl is the unbalanced turning moment, I is the moment of inertia of the body ($\int y^2 dm$) and ω_0 and is the initial angular velocity.

General Rule for Rotating Bodies. Determine all the external forces acting and their moments about the axis of rotation. If these moments are balanced, there will be no change of motion. If the moments are unbalanced, this unbalanced moment or **torque** will cause an angular acceleration about the axis.

Rotation About an Axis Passing Through the Center of Gravity. The rotation of a body about its center of gravity can only be caused or changed by a **couple**. See Fig. 75. If a single force F is applied to the rim of the wheel, the axis immediately acts on the wheel with an equal force to prevent translation, and the result is a couple (moment Fr) acting on the body and causing rotation about its center of gravity. **The work done by the couple causing rotation** is $M\theta$, where M is the moment of the couple and θ is the angular space passed over, in radians. **If there is no unbalanced moment there must exist either rest or uniform rotation.**

FIG. 75.

In calculations pertaining to **hoisting machinery**, it is sometimes necessary to determine the total weight to be accelerated. This consists of the combined weight of the load to be hoisted, the rope or chain and the cage or skip (if used) *plus* a certain weight w_1 equivalent to that of the hoisting drum if concentrated at a point in its circumference. This latter may be determined as follows: Energy in ft-lb of rotating drum $= E = I\omega^2/2 = w\omega^2r^2/2g$, where r = radius of gyration of drum, in ft; ω = angular velocity, and w = weight in lb. The product wr^2 is sometimes known as the **flywheel effect**. Let R = radius of drum from shaft axis to rope center, in ft. Then, considering the weight concentrated at radius R, for the same quantity of energy, $E = w_1\omega^2R^2/2g$, whence $w_1R^2 = wr^2$, or $w_1 = wr^2/R^2$. For example, in a large electric mine hoist, $w = 16{,}000$ lb, $r = 6.4$ ft and $R = 8$ ft. $\therefore$ equivalent weight at $R = w_1 = (16{,}000 \times 6.4 \times 6.4)/(8 \times 8) = 10{,}240$ lb.

Combined Rotation and Translation. Any body that is revolving about an axis *not* passing through its center of gravity may be considered *to have a motion of translation and a motion of rotation about* its center of gravity combined. The body shown in Fig. 76 is revolving about C with an angular velocity ω, but this motion may be considered to be made up of a translation with the velocity ωl of the center of gravity of the body about C and a revolution about the center of gravity with the same angular velocity (ω) as that with which the body rotates about C.

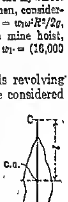

FIG. 76.

The kinetic energy of the body is $\omega^2 I/2$, in which I is the moment of inertia of the body with respect to C. This is the same as $\frac{1}{2}mv^2 + \omega^2 I_0/2$, where $v = \omega l$ and I_0 = moment of inertia of the body with respect to an axis passing through its center of gravity and parallel to the axis at C. The motion of translation requires a single force applied at the center of gravity of the body, and the motion of rotation about the center of gravity requires the action of a couple, therefore the combined motion must be caused by the resultant of a single force and a couple.

The point of application of this resultant is known as the **center of percussion** and may be defined as the point of application of the resultant of

$60 + 32 - 80 - 5.6 = 6.4$ lb and acts downward

$$F = ma = (100/g)a \therefore a = 0.064g$$

The body is acted upon by constant forces and starts from rest, therefore, $v = at$ and $s = \frac{1}{2}at^2$. If $t = 5$, $v = 0.064g \times 5 = 0.32g$, $s = (1/2)0.32g \times 5 = 0.8g$; taking $g = 32.16$, $v = 0.32 \times 32.16 = 10.29$ ft per sec, $s = 0.8 \times 32.16 = 25.73$ ft.

(b) Find the constant force necessary to start from rest a train weighing 100 tons and give it a speed of 30 mph in 1 min; track to be level and straight, train resistance to be constant and equal to 12 lb per ton. The external forces acting upon the train are the resistance of $100 \times 12 = 1200$ lb, the constant force F pulling the train along the level track, the force of gravity equal to weight of train, and the reaction of the track. The forces normal to the track form a balanced system, but, as the train is to be started from rest and given a velocity, the forces acting along the track must form an unbalanced system. A velocity of 30 mph = 44 fps; to acquire this velocity in 60 sec requires an acceleration of 44/60, as $a = v/t$. The unbalanced force to give the train this acceleration is $F = ma = (100 \times 2000/g)(44/60) = 4580$ lb. The total tractive force required is therefore $4580 + 1200 = 5780$ lb. If the train is on a grade, the problem is the same, with the addition of another force acting along the track, that is, the component of the weight along the track.

The so-called laws of inclined planes are simply derived by the above method. In Fig. 64 the weight W slides down the plane without friction. The unbalanced component of the forces acting along the plane is $W \sin B$, $\therefore a = g \sin B$, $v = (g \sin B)t$, and $s = (\frac{1}{2}g \sin B)t^2$ as the body starts from rest. The time necessary to pass over a distance s is $t = \sqrt{2s/g \sin B}$, and $v = at = \sqrt{2gs \sin B} = \sqrt{2gH}$, showing that if the body slides without friction from T to A, its velocity will be the same as if it fell through the same vertical distance TN. With initial velocity v_0, $v = v_0 \pm (g \sin B)t$, and $s = v_0t + (\frac{1}{2}g \sin B)t^2$.

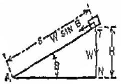

FIG. 64.

Tension in a Rope Connected to a Moving Body. The force with which the rope acts on the body is equal and opposite to the force with which the body acts on the rope, and each is equal to the tension in the rope. In Fig. 65, neglecting the weight of pulley A and the cord, find the tension in the cord. The unbalanced force acting on the two weights is $20 - 5 = 15$ lb and acts on the two weights. $\therefore 15 = (25/g)a$, and $a = 3g/5$. w_1 is accelerated in an upward direction and w_2 downward. $T_1 = w_1 +$ the unbalanced force necessary to give w_1 an upward acceleration of $(3g/5) = 5 + (5/g) \times (3g/5) = 8$ lb. $T_2 = w_2 -$ the unbalanced force necessary to give w_2 a downward acceleration of $(3g/5) = 20 - (20/g) \times (3g/5) = 8$ lb. If a body is moved uniformly upward by a rope, the tension in the rope is equal to the weight of the body, without regard to the velocity.

FIG. 65.

If a weight is to be pulled up an inclined plane by means of a rope, the tension in the rope is equal to the component of the weight along the plane plus the normal pressure between the surfaces times the coefficient of friction, plus the unbalanced force necessary to give the weight the acceleration that it has. If the weight is to move uniformly up the plane there will be no acceleration, and the tension in the rope must simply balance all resistance to motion.

Harmonic Motion

Forces Necessary to Cause Harmonic Motion. In Fig. 66, point A moves uniformly in the circle $X'YXY'$, and point P moves to and fro along $X'CX$.

$(w_1 + w_2)a/g$ is the unbalanced force necessary to give the two weights the acceleration a, and $a_a I$ is the unbalanced moment necessary to give the pulley the angular acceleration a_a. If there is no slipping, $a_a = a/r$.

Relation between the Center of Percussion and Radius of Gyration. $l = I/mx_0 = k^2/x_0 \therefore k^2 = x_0 l$; where k = radius of gyration. Therefore the radius of gyration is a mean proportional between the distance from the axis of oscillation to the center of percussion and the distance from the same axis to the center of gravity.

Interchangeability of Center of Percussion and Axis of Oscillation. If a body is suspended from an axis, the center of percussion for that axis can be found. If the body be suspended from this center of percussion as an axis, the original axis of suspension will then become the center of percussion. The center of percussion is sometimes known as the **center of oscillation.**

Time of Oscillation of a Compound Pendulum. The length of an equivalent simple pendulum is the distance from the axis of suspension to the center of percussion of the body in question. To find the **time of oscillation** of a body about a given axis, find the distance $l = I/mx_0$ from that axis to the center of percussion of the swinging body. The length of the simple pendulum that will oscillate in the same time is this distance l. The time of oscillation for the equivalent single pendulum is $t = \pi\sqrt{l/g}$. This is the time necessary for a single swing, not over and back.

Determination of Moment of Inertia by Experiment. To find the moment of inertia of a body, suspend it from some axis not passing through the center of gravity and, by swinging it, determine the time of a single oscillation in seconds. The known values will then be t = time of single oscillation, x_0 = distance from axis to center of gravity, and m = mass of rod. The length of the equivalent simple pendulum is $l = I/mx_0$. Substituting this value of l in $t = \pi\sqrt{l/g}$ gives $t = \pi\sqrt{I/mx_0g}$, from which $t^2 = \pi^2 I/mx_0g$, or $I = mx_0gt^2/\pi^2$.

Impulse and Momentum

Impulse of a force $= F(t_2 - t_1)$ when the force is constant and $t_2 - t_1$ is the time interval during which it acts. If the force is not constant in magnitude but always acts in the same direction, impulse $= \int_{t_1}^{t_2} F dt$.

Impulses may be added algebraically by means of a polygon, or an impulse may be resolved into components by means of a parallelogram. The moment of an impulse may be found in the same manner as the moment of a force by representing the impulse by a line and taking the product of the magnitude of the impulse by the perpendicular distance from the line representing it to the point about which the moment is to be taken.

Momentum. The momentum of a particle is mv, where m = mass of the particle and v = its velocity. Momentums can be represented by lines (vectors) and added and resolved in the same manner as forces by means of polygon and parallelogram. The moment of momentum can be determined by the same methods as used for the moment of a force or moment of an impulse, the momentum being represented by a line. **Angular momentum** is the product of the component of momentum at right angles to the radius, and the radius.

Impact

The straight line perpendicular to the common contact plane of two colliding bodies and passing through the point of contact is called the

must be done to overcome resistance. The difference of these areas, or *EFGDE*, will represent work done in excess of that required to overcome resistance, and consequently is equal to the increase in kinetic energy. Equating the work represented by the area *EFGDE* to $\frac{1}{2}wv^2/g$ and solving for v, will give the required velocity at B. If the body did not start from rest this area would represent the change in kinetic energy, and the velocity could be obtained by the formula: Work $= \frac{1}{2}(w/g)(v_1^2 - v_0^2)$, v_1 being the required velocity.

If the forces acting upon a body are functions of the time, a diagram similar to Fig. 67 may be drawn using *time* as abscissas. In this case the areas represent the impulses of the forces. The area *EFGDE* will then represent the unbalanced impulse and therefore the change in momentum and the velocity v_1 can be determined by placing this area equal to $w/g(v_1 - v_0)$.

General Rule for Rectilinear Motion. Resolve each force acting on the body into components, one of which acts along the line of motion of the body and the other at right angles to the line of motion. Take the sum of all the components acting in the direction of the motion and multiply this sum by the distance moved through for constant forces. (Take the average force times distance for forces that vary.) This product will be the total work done upon the body. If there is no unbalanced component there will be no change in kinetic energy and consequently no change in velocity. If there is an unbalanced component, the change in kinetic energy will be this unbalanced component multiplied by the distance moved through.

Conservation of Energy. The sum of the kinetic and potential energies of a body acted on by gravity alone is constant.

If a body is at a certain height h above the ground and is motionless, its potential energy is equal to the work done in raising it to that height. If the body falls to the ground its velocity v when it strikes will be $\sqrt{2gh}$, and its kinetic energy will be $wv^2/2g$. The potential energy before starting to drop is, therefore, the same as its kinetic energy when it reaches the earth. At any point during its fall its total energy, obtained by adding the kinetic and potential energies, will be the same $wv^2/2g$, where v is the velocity that the body would have if it fell freely to the earth from the original height.

The work done by a system of forces acting on a body is equal to the algebraic sum of the work done by each force taken separately.

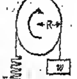

Fig. 68.

Power is the rate at which work is performed, or the number of units of work performed in unit time. The units of power employed by engineers are the **horse power**, or 33,000 ft-lb per min = 550 ft-lb per sec, and the **kilowatt** = 1.341 hp = 737.55 ft-lb per sec.

Friction Brake. In Fig. 68 a pulley revolves under the band and in direction of the arrow, exerting a pull of T on the spring. The friction of the band on the rim of the pulley is $(T - w)$, where w is the weight attached to one end of the band. Let the pulley make N rpm; then the work done per minute against friction by the rim of the pulley is $2\pi RN(T - w)$, and the horse power absorbed by brake $= 2\pi RN(T - w)/33,000$.

Centrifugal Force

Centrifugal and Centripetal Forces. When a body revolves about an axis, some connection must exist capable of applying force enough to the body to constantly deviate it toward the axis. This deviating force is known as **centripetal force.** The equal and opposite resistance offered by

The **strength** or **intensity of the field** at any given point is the relation between a force F acting on a mass m at that point and the mass. Intensity of field $= i = F/m$; $F = mi$.

The **unit of field intensity** is the same as the unit of acceleration, *i.e.*, 1 ft per sec per sec, or 1 m per sec per sec. The intensity of a field of force may be represented by a line (or **vector**).

A field of force is said to be **homogeneous** when the intensity of all points is uniform and in the same direction.

A field of force is called a **central field of force** with a center O, if the direction of the force acting on the mass particle m in every point of the field passes through O and its magnitude is a function only of the distance r from O to m. A line so drawn through the field of force that its direction coincides at every point with that of the force prevailing at that point, is called a **line of force**.

Law of Gravitation. Two particles attract each other with a force F proportional to their masses m_1 and m_2 and inversely proportional to the square of the distance r between them, or $F = km_1m_2/r^2$, in which k is the **gravitation constant**, or the force with which two spheres of unit mass attract each other through unit distance. The value of gravitation constant is $k = 6.66 \times 10^{-8}$ cm^3 g^{-1} sec^{-2} in cgs units, or $k = 3.44 \times 10^{-8}$ ft^4 lb^{-1} sec^{-4} in engineering units. The **density of a body** is its mass per unit of volume. Density $= d =$ mass/volume.

THE GYROSCOPE

By E. V. HUNTINGTON

The elementary facts about gyroscopic forces may be briefly illustrated by the following example. Given, a wheel or disk, of weight w and radius R, spinning rapidly about its axis OA (Fig. 1), and mounted in gimbal rings in such a way that its center is stationary, while its axis is free to point in any

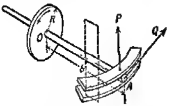

FIG. 1.

FIG. 2.

direction in space. (See Fig. 2.) Let $k =$ the radius of gyration of the wheel about its axis. (If all the weight is in the rim, $k^2 = R^2$; if the wheel is a homogeneous disk, $k^2 = R^2/2$.) Now suppose the axle end A is constrained to move between two smooth fixed guides, forming a slot as in Fig. 1, and suppose that a force Q is applied to pull the point A along the slot. Then, (1) as far as the motion of A along the slot is concerned, it makes no difference whether the disk is rotating or not; in fact, $Qb = (w/g)(k^2/2)(dv/bdt)$, where Qb is the moment of Q about the center O, and dv/dt is the (linear) acceleration of the point A along the slot; but (2) if the wheel is rotating, then the mere motion of A along the slot will call into play a strong lateral pressure P (called a gyroscopic reaction) against one of the guides.

Balancing

A rotating body is said to be in **standing balance** when its center of gravity coincides with the axis upon which it revolves. Standing balance may be obtained by resting the axis carrying the body upon two horizontal plane surfaces, as in Fig. 72. If the center of gravity of the wheel A coincides with the center of the shaft B, there will be no movement, but if the center of gravity does not coincide with the center of the shaft, the shaft will roll until the center of gravity of the wheel comes directly under the center of the shaft. The center of gravity may be brought to the center of the shaft by adding or taking away weight at proper points on the diameter passing through the center of gravity and the center of the shaft. Weights may be added to or subtracted from any part of the wheel so long as its center of gravity is brought to the center of the shaft.

FIG. 72.

A rotating body may be in standing balance and not in **running balance.** In Fig. 73, AA and BB are two disks whose centers of gravity are at o and p, respectively. The shaft and the disks are in standing balance if the disks are of the same weight and the distances of o and p from the center of the shaft are equal, and o and p lie in the same axial plane but on opposite sides of the shaft. Let the weight of each disk be w and the distances of o and p from the center of the shaft each be equal to r. The force exerted on the shaft by AA is equal to $w\omega^2r/g$, where ω is the angular velocity of shaft. Also, the force exerted on shaft by $BB = w\omega^2r/g$. These two equal and opposite parallel forces act at a distance x apart, and constitute a couple with a moment tending to rotate the shaft, as shown by the arrows, of $(w\omega^2r/g)x$. A couple cannot be balanced by a single force, so two forces at least must be added to or subtracted from the system to get running balance.

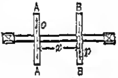

FIG. 73.

Curvilinear Motion

An unresisted projectile has a motion compounded of the vertical motion of a falling body, and of the horizontal motion due to the horizontal component of the velocity of projection. In Fig. 74 the only force acting after the projectile starts is gravity, which causes an acceleration downward. The horizontal component of the original velocity v_0 is not changed by gravity. The projectile will rise until the velocity given to it by gravity is equal to the vertical component of the starting velocity v_0, and the equation $v_0 \sin a = gt$, gives the time t required to reach the highest point in the curve. The same time will be taken in falling if the surface XX is level, and the projectile will therefore be in flight $2t$ sec. The distance $s = v_0 \cos a \times 2t$, and the maximum height of ascent $h = (v_0 \sin a)^2/2g$. The expressions for the co-ordinates of any point on the path of the projectile are: $x = (v_0 \cos a)t$, and $y = (v_0 \sin a)t - \frac{1}{2}gt^2$, giving $y = x \tan a - (gx^2/2v_0^2 \cos^2 a)$ as the equation for the curve of the path. The radius of curvature of the highest point may be found by using the general expression C. F. $= wv^2/gr$ and solving for r, v being taken equal to $v_0 \cos a$.

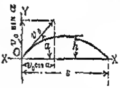

FIG. 74.

Simple Pendulum. The time of a single oscillation in one direction $= t = \pi\sqrt{l/g}$, where l is the length of the pendulum and the length of the swing is not great as compared to l.

STRESSES IN FRAMED STRUCTURES

BY

A. HAERTLEIN

(Originally prepared by H. W. Hayward)

An ideal truss is a framework consisting of straight bars or members connected at their ends by frictionless pins. The external forces are applied only at these pins. Internal forces or stresses in such straight bars are axial, either tension or compression, without bending. Since frictionless pins are impossible and the ends of bars are often riveted or welded, the ideal truss is never realized. For purposes of analysis, the primary stresses, which are always axial, are determined on the assumption that the truss under consideration conforms to the ideal. Secondary stresses are additional stresses, generally flexural or bending, brought about by all the factors that make the actual truss different from the ideal. In the following discussion, primary stresses will be considered.

General Procedure. After all external forces, loads, and reactions have been determined, the internal force or stress in any member is found (1) by

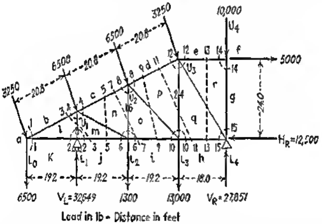

FIG. 1.

taking a section, making an imaginary cut through the members of the truss, including the one whose stress is to be found, so as to separate the truss into two parts; (2) by isolating either of these parts; (3) by replacing each bar cut by a force, representing the stress in the bar or the force required to come to the part of the truss isolated from the other part removed; and (4) by applying the equations of statics to the part isolated.

The various ways in which sections can be taken and the equations used to determine the stresses are illustrated by a solution of the truss (Fig. 1).

Stress in bl and lk. Section 1-1. Isolate part to left [Fig. 2(*a*)]. Assume the unknown stresses in *bl* and *kl* as tension. Since the forces are concurrent and coplanar, only two independent equations of statics are available. These may be either $\Sigma x = 0$ and $\Sigma y = 0$, or $\Sigma M = 0$ taken about two different points selected so that neither point is the intersection of the forces, or so that the line joining the two points is not coincident with either of the unknown internal forces.

Using the first set of equations and taking components of all forces along a horizontal and vertical axis, for example, the horizontal component of the 3,250 lb force is 1,250

all the forces tending to cause a body to rotate about a certain axis. It is the point at which a suspended body may be struck without causing any pressure on the axis passing through the point of suspension.

Center of Percussion. The distance from the axis of suspension to the center of percussion is $l = I/mx_0$, where I = moment of inertia of the body about its axis of suspension, m = total mass of the body and x_0 = distance from the axis of suspension to the center of gravity of the body.

Examples. (1) Find the center of percussion of the homogeneous rod (Fig. 77) of length L and mass m, suspended at XX.

$$l = \frac{I}{mx_0};\quad I(\text{approx}) = \frac{m}{L}\int_0^L x^2dx;\quad x_0 = \frac{L}{2};\quad \therefore l = \frac{2}{L^2}\int_0^L x^2dx = 2L/3.$$

(2) Find the center of percussion of a solid cylinder, of mass m, resting on a horizontal plane. In Fig. 78, the instantaneous center of the cylinder is at A. The center of percussion will therefore be a height above the plane equal to $l = I/mx_0$. Since $I = (mr^2/2) + mr^2$ and $x_0 = r$, $l = 3r/2$.

Fig. 77.

(3) In Fig. 79, a solid cylinder weighing 100 lb is moved along a horizontal plane by a horizontal force of 12 lb applied at the axis. If the cylinder rolls without slipping, how far may it be moved in 10 sec and what must be the friction?

The forces acting are F, gravity, and the reaction of the plane. The vertical component of the reaction of the plane balances gravity, leaving the horizontal component of the reaction of plane and F as the forces causing rotation about the instantaneous center O. The resultant R of the 12 lb force and the friction must be applied at the center of percussion, which is at the distance I/mx_0 from O or 3 ft. The resultant can be found by taking moments about O, $3R = 2 \times 12$; $\therefore R = 8$ lb. The friction must be $12 - 8 = 4$ lb acting to the left, because 8 lb is the resultant of $F = 12$ lb and the friction. This resultant of 8 lb at a distance of 3 ft from O has the same effect as the two forces of 12 lb and 4 lb acting together. This single force of 8 lb must be also the resultant of a couple and a single force at the axis, see Fig. 79(b). The single force of 8 lb acting to the right at the axis causes translation, and the couple whose moment is 8×1 causes rotation about the center of gravity.

Fig. 78.

The linear acceleration along the plane is found by using the 8 lb force. $F = ma$ $\therefore 8 = 100a/g$, $a = 8g/100$, and $v = (8g/100) \times 10 = (4g/5)$ fps. $S = \frac{1}{2}(80g/100) \times 10$.

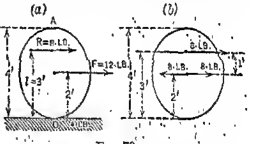

Fig. 79.

Wheel or Cylinder Rolling Down a Plane. In this case the component of the weight along the plane tends to make it roll down, and is treated as a force causing rotation. The forces acting on the body should be resolved into components along the line of motion and perpendicular to it. If the forces are all known, their resultant is at the center of percussion. If one force is to be determined (the exact conditions as regards slipping or not slipping must be known), the center of percussion can be determined and the unknown force found.

When weights act as shown in Fig. 80, where the pulley over which the ropes run has appreciable weight, it is necessary to take into account the moment of the force required to accelerate the pulley itself.

Fig. 80.

In Fig. 80, the unbalanced force $w_1 - w_2$ is accelerating the pulley as well as the two weights. Therefore, $w_1 - w_2 = (w_1 + w_2)(a/g) + a_0I/r$, where

Stress in bars cn and nm. Section 4-4. Cut the members around the pin at U_1 and so use $\Sigma x = 0$ and $\Sigma y = 0$ for concurrent forces on the upper part of the cut isolated [Fig. 2(*d*)]. It will be observed that there cannot be more than two unknown stresses in the section taken around a pin or point in order to have the stresses determined from the equations of statics. Hence the sections cannot be taken at random, for example, section 6-6 could not be taken at this time because the stresses in bar *mn*, *no*, and *oi* are unknown. The numerical work is generally made easier by resolving the forces into components parallel to the axes which may be selected in any convenient direction. For this particular case, the x-axis is taken as horizontal and the y-axis perpendicular to it.

$$\Sigma x = 0 = s_{cn}\ 19.2/20.8 + s_{mn}\ 19.2/20.8 + 2500 - 24{,}700 \times 19.2/20.8$$
$$\Sigma y = 0 = s_{cn}\ 8/20.8 - s_{mn}\ 8/20.8 - 6000 + 32{,}649 - 24{,}700 \times 8/20.8$$

Solving these equations simultaneously, $s_{cn} = 11{,}298$ compression
$s_{mn} = 33{,}290$ tension

By taking section 5-5 and considering the part to the left [Fig. 2(*e*)]

ΣM about $L_0 = 0 = s_{mn} \times 8/20.8 \times 38.4 + 2500 \times 8 - (32{,}649 - 6000)19.2$
ΣM about $U_1 = 0 = -s_{mj} \times 8 - 1250 \times 8 - 9500 \times 19.2$
ΣM about $L_2 = 0 = s_{cn} \times 19.2/20.8 \times 18 + 2500 \times 8 - 9500 \times 38.4 + 26{,}649 \times 19.2$

from which $s_{mn} = 33{,}290$ tension, $s_{mj} = 24{,}050$ compression, and $s_{cn} = 11{,}298$ compression.

Stress in bars no and oi. Section 6-6. Consider the part around the pin L_2 [Fig. 2(*f*)]

$$\Sigma x = 0 = s_{oi} + 24{,}050 - 33{,}290 \times 19.2/20.8;\ s_{oi} = 6{,}679 \text{ tension}$$
$$\Sigma y = 0 = s_{no} + 33{,}290 \times 8/20.8 - 13{,}000;\ s_{no} = 195 \text{ tension}$$

Or by taking section 7-7 and considering the part to the left Fig. 2(*g*)

ΣM about $L_0 = 0 = -s_{no} \times 38.4 + 2500 \times 8 - 26{,}649 \times 19.2 + 13{,}000 \times 38.4$
ΣM about $U_2 = 0 = -s_{oi} \times 18 - 1250 \times 16 - 2500 \times 8 - 9500 \times 38.4 + 26{,}649 \times 19.2$

from which $s_{no} = 196$ tension and $s_{oi} = 6{,}679$ tension.

Stresses in bars dp and op. Section 8-8. Consider the part around the pin U_2 [Fig. 2(*h*)]

$$\Sigma x = 0 = s_{dp} \times 19.2/20.8 + s_{op} \times 19.2/24.99 + 2500 + 11{,}298 \times 19.2/20.8$$
$$\Sigma y = 0 = s_{dp} \times 8/20.8 - s_{op} \times 16.0/24.99 - 6105 + 11{,}298 \times 8/20.8$$

from which $s_{dp} = 7734$ compression and $s_{op} = 7535$ compression, or by taking section 9-9 and considering the section to left [Fig. 2(*i*)]

ΣM about $L_3 = 0 = s_{dp} \times 19.2/20.8 \times 24 + 2500(8 + 16) - 6000(19.2 + 38.4) - 9500 \times 57.6 - 13{,}000 \times 19.2 + 32{,}649 \times 38.4$
ΣM about $L_0 = 0 = s_{op} \times 16/24.99 \times 57.6 + 2500(8 + 16) - 26{,}649 \times 19.2 + 19{,}000 \times 38.4$
ΣM about $U_2 = 0 = -s_{oi} \cdot 16 - 1250 \times 16 - 2500 \times 8 - 9500 \times 38.2 + 26{,}649 \times 19.2$

from which $s_{dp} = 7{,}733$ compression, $s_{op} = 7{,}538$ compression, and $s_{oi} = 6{,}679$ tension.

Stresses in bars pq and qh. Section 10-10. Consider the part around the pin L_3 [Fig. 2(*j*)]

$$\Sigma x = 0 = s_{qh} + 7538 \times 19.22/24.99 - 6679;\ \text{from which } s_{qh} = 881 \text{ tension}$$
$$\Sigma y = 0 = s_{pq} - 13{,}000 - 7538 \times 18/24.99;\ \text{from which } s_{pq} = 17{,}826 \text{ tension}$$

Or taking section 11-11 and considering the portion to the right because it has the fewer forces acting on it [Fig. 21(*k*)].

ΣM about $L_6 = 0 = s_{pq} \times 57.6 + 6250 \times 24 + 3000 \times 57.6 - (27{,}851 - 10{,}000)75.6$
ΣM about $L_3 = 0 = -s_{dp} \times 19.2/20.8 \times 24 + 6250 \times 24 - 17{,}851 \times 18$
ΣM about $U_3 = 0 = s_{qh} \times 24 + 12{,}500 \times 24 - 17{,}851 \times 18$

from which $s_{pq} = 17{,}825$ tension, $s_{dp} = 7{,}733$ compression, and $s_{qh} = 888$ tension.

Stresses in er and rq. Section 12-12. Consider one part around U_3 [Fig. 2(*l*)]

$$\Sigma x = 0 = s_{er} + s_{rq} \times 18/30 + 7733 \times 19.2/20.8 + 1250$$
$$\Sigma y = 0 = -s_{rq} \times 24/30 + 7733 \times 8/20.8 - 20{,}825$$

line of impact. If the centers of gravity of the bodies lie on this line, the impact is called **central impact**; in any other case, **eccentric impact**. If the directions of the motions of the two bodies coincide with the line of impact, the impact is said to be **direct**; in any other case, **oblique**.

Direct Central Impact. When two masses m_1 and m_2 having velocities u_1 and u_2 and moving in the same line meet each other, the relation between the velocities u_1 and u_2 before and v_1 and v_2 after collision is expressed by the equation: $m_1v_1 + m_2v_2 = m_1u_1 + m_2u_2$. If $v' =$ velocity of m_1, $v'' =$ velocity of m_2 at any time during impact, and $v =$ common velocity at instant of greatest compression, $m_1v_1 + m_2v_2 = m_1u_1 + m_2u_2 = m_1v' + m_2v''$, and $v = (m_1u_1 + m_2u_2)/(m_1 + m_2)$. **The sum of the momentums of the two masses before, after, and during impact is the same.**

A second relation between the velocities is $e = (v_2 - v_1)/(u_1 - u_2)$, e being called the **coefficient of impact**, or the **coefficient of restitution.** Its value depends on the elastic or plastic properties of the bodies which come in collision, being 0 for inelastic bodies (nearly 0 for soft substances such as putty or lead) and 1 for perfectly elastic bodies.

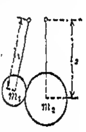

FIG. 81.

To determine the coefficient of restitution between two materials, let m_2 be so large in comparison to m_1 that it may be considered as infinite, *e.g.*, a foundation weighing many tons and a ball weighing a few ounces. Let m_2 be stationary, making u_2 and $v_2 = 0$; the formula $e = (v_2 - v_1)/(u_1 - u_2)$ will then reduce to $e = -v_1/u_1$. Drop the ball from the height H upon m_2 and note the rebound h. Then $u_1 = \sqrt{2gH}$ downward and $v_1 = \sqrt{2gh}$ upward, and $e = -v_1/u_1 = \sqrt{h/H}$. For central impact when the bodies are swinging (see Fig. 81), $v_1 + eu_1 = v_2 + eu_2$, and also if I_1 and $I_2 =$ moments of inertia of m_1 and m_2, $(I_1v_1/l_1^2) + (I_2v_2/l_2^2) = (I_1u_1/l_1^2) + (I_2u_2/l_2^2)$.

Impact of Perfectly Inelastic Bodies. The two masses move after the impact with a common velocity $u = u_1 = u_2 = (m_1v_1 + m_2v_2)/(m_1 + m_2)$, and **the loss of kinetic energy due to impact** $= E = \frac{1}{2}m_1m_2(v_1 - v_2)^2/(m_1 + m_2)$.

If $v_2 = 0$, $u = m_1v_1/(m_1 + m_2)$ and the loss of energy $= \frac{1}{2}m_1m_2v_1^2/(m_1 + m_2)$

Perfectly Elastic Impact. In this case, the loss of energy $E = 0$. The velocities after impact become: $u_1 = v_1 - [2m_2(v_1 - v_2)/(m_1 + m_2)]$, and $u_2 = v_2 + [2m_1(v_1 - v_2)/(m_1 + m_2)]$. For $v_2 = 0$, $u_1 = (m_1 - m_2)v_1/(m_1 + m_2)$, and $u_2 = 2m_1v_1/(m_1 + m_2)$; there is no loss of energy and the body m_1 retraces its path.

Imperfectly Elastic Impact. If the coefficient of impact is e, $u_1 = v_1 - [m_2(1 + e)(v_1 - v_2)/(m_1 + m_2)]$; $u_2 = v_2 + [m_1(1 + e)(v_1 - v_2)/(m_1 + m_2)]$. Loss of energy $= m_1m_2(1 - e^2)(v_1 - v_2)^2/2(m_1 + m_2)$.

When a jet of water strikes a flat plate perpendicularly to its surface, the force exerted by the water on the plate is wv/g, where w is the weight of water striking the plate in a unit of time and v is the velocity. When the jet is inclined to the surface by an angle A, the pressure is (wv/g) cos A.

Fields of Force—Attraction

The space within which the action of a physical force comes into play on bodies lying within its boundaries is called **the field of the force.**

HB is of the same magnitude as for the lower joint but acts in the opposite direction. The stress in the member *kh* is *KH* and is therefore compression.

Problem. The truss shown in Fig. 7 is loaded with a dead load of 21,760 lb. uniformly distributed over the upper chord, together with a wind load of 13,600 lb on the right side. Both ends of the truss are fixed and the horizontal components of the supporting forces are assumed to be equal. The supporting forces may be determined graphically by first assuming a roller under one end of the truss, or by the funicular polygon construction (see p. 203). They are often calculated and the polygon of external forces plotted from the results of the calculation. This is a desirable method, as it offers a check on this most important part of the graphical work.

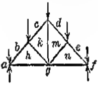

Fig. 5.

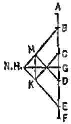

Fig. 6.

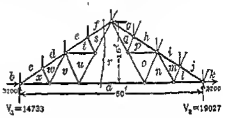

Fig. 7.

The horizontal component of the wind load is $(16/34)13{,}600 = 6400$ lb. The *H* component of each supporting force is assumed to be $6400/2 = 3200$ lb. The vertical component of the wind load is $(30/34)13{,}600 = 12{,}000$ lb. Taking moments about the right end of the truss, $(21{,}760 \times 30) + (13{,}600 \times 17) = 60V_1$. $\therefore V_1 = 14{,}733$; $V_2 = 21{,}760 + 12{,}000 - 14{,}733 = 19{,}027$.

The polygon of external forces can now be constructed, as in Fig. 8. The dotted part of the diagram is the combination of the dead and wind loads, assuming that they

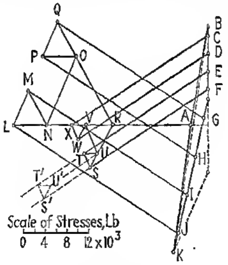

Fig. 8.

are each concentrated. The dotted line *BK* is the resultant of these loads. The supporting forces *KA* and *AB* are determined by plotting to scale their horizontal and vertical components as calculated. The polygon of external forces for the truss is *BCDEFGHIJKAB*, and must check with the polygon shown dotted. The forces *GH*, *HI*, *IJ*, and *JK* are the resultants of the forces acting at the joints on the right side of the truss.

Which one of the two guides the force P will act against depends on the direction of spin, and is best determined by the following rule (E. V. Huntington, *Eng. News*, July 21, 1910): If the applied force Q is thought of as due to the pressure of a flat board against the side of the revolving axle (the board being perpendicular to Q as shown in dotted line in Fig. 1), then the axle will strive to move in the direction in which it would naturally roll if the board were rough. Thus, in Fig. 1, the axle end A will push against the *upper* guide, and would actually move in the direction of the P arrow if the guide were not present.

The magnitude of the gyroscopic force P at any instant is proportional to the spinning velocity, and also to the velocity of A along the slot, being given by

$$Pb = (w/g)k^2(\pi N/30)(v/b),$$

where Pb = the moment of P about the center, v = the linear velocity of the point A along the slot at the instant in question, N = rpm in the spinning velocity of the wheel, and g = 32.17 ft per sec per sec.

It should be noted that the gyroscopic reaction P against the fixed guide does not depend on the magnitude of the accelerating force Q, except in so far as Q is necessary to create the velocity v, in case A starts from rest; when once the velocity v has been established, Q can be made zero, and both v and P will (neglecting friction) continue constant. On the other hand, if the guide is movable, and exerts a pressure $P' = P$ against the axle at A, this force will itself maintain the velocity v (called the precessional velocity) of the point A along the guide. In brief, *the end of the axle of a rotating gyroscope always tends to move at right angles to any force impressed upon it.*

For example, suppose an airplane is driven by a right-handed propeller (turning like a right-handed screw when moving forward); if a gust of wind or other force turns the machine to the *left*, the gyroscopic action of the propeller will make the forward end of the shaft strive to *rise*; if the wing surface is large, this motion will be practically prevented by the resistance of the air, and the gyroscopic forces become effective merely as internal stresses, whose maximum value can be computed by the formula above. Similarly, if the airplane is dipped *downward*, the gyroscopic action will make the forward end of the shaft strive to turn to the *left*.

In the Brennan monorail car, the slot is parallel to the rail, so that a force Q, applied automatically at the axle end when the car starts to tip, will be converted gyroscopically into a strong righting moment Pb, which forces the car back into a position of lateral equilibrium. Numerical case: If w = 3200 lb, k = 1.4 ft, b = 2 ft, and spinning velocity = 3000 rpm, then a force Q of 50 lb acting for ½ sec will produce at the end of that time a precessional velocity of 1 ft per sec along the slot, with a resulting lateral force against the guide of nearly 16,000 lb. The displacement of the point A along the slot will be about 6 deg. An essential feature of the apparatus is a device for bringing the axle back into the ready position after each period of activity.

Other applications are the Whitehead torpedo, the Schlick and the Sperry ship-steadying devices, the gyrocompass and automatic steering mechanism for ships, the artificial horizon and the directional gyro for aircraft, and the "gyropilot," which automatically keeps an airplane on its course. These devices are made by the Sperry Gyroscope Co. For the mathematical theory of the gyroscope, see H. Crabtree, "Spinning Tops and Gyroscopic Motion," Longmans. See also Deimel, "Mechanics of the Gyroscope," Macmillan.

FRICTION

REVISED BY

GEORGE B. KARELITZ

(Previously revised by Guido H. Marx)

REFERENCES: Archbutt and Deeley, "Lubrication and Lubricants," Griffin. Stanton, "Friction," Longmans. Bevan, "Theory of Machines," Longmans. Heck, "Kinematics and Dynamics of Machinery," McGraw-Hill. Nash and Bowen, "The Principles and Practice of Lubrication," Chapman-Hall. "General Discussion on Lubrication and Lubricants," A.S.M.E.

Friction is the resistance that is encountered when two solid surfaces slide or tend to slide over each other. The surfaces may be either dry or lubricated. In the first case, when the surfaces are free from contaminating fluids, the resistance is called **dry friction.** The friction of brake shoes on the rim of a wheel, of a dry grinding stone on the worked metal, and of a pier on its foundation are examples of dry friction.

When the rubbing surfaces are separated from each other by a very thin film of lubricant, the friction is that of **boundary (or greasy) lubrication.** The lubrication depends in this case on the strong adhesion of the lubricant to the material of the rubbing surfaces; the layers of lubricant slip over each other instead of the dry surfaces. A journal turning at very low-speed under a heavy load, or the parallel guides in a machine tool, are representative instances of boundary lubrication.

When the lubrication is arranged so that the rubbing surfaces are separated by a fluid film, and the load on the surfaces is carried entirely by the hydrostatic pressure in the film, the friction is that of **complete** (or **viscous**) **lubrication.** In this case, the frictional losses are due solely to the internal fluid friction in the film. Oil ring bearings, bearings with forced feed of oil, and pivoted-shoe-type thrust bearings operating in an oil bath are instances of complete lubrication.

Incomplete lubrication takes place when the load on the rubbing surfaces is carried partly by a fluid viscous film and partly by areas of boundary lubrication. The friction is intermediate between that of fluid and boundary lubrication. Incomplete lubrication exists in bearings with drop-feed lubrication or on the guides of a crosshead.

Static and Sliding Coefficients of Friction

In the absence of friction, the resultant of the forces between the surfaces of two bodies pressing upon each other is normal to the surface of contact. With friction, the resultant deviates from the normal.

If one body is pressed against another by a force P, as in Fig. 1, the first body will not move provided the angle α_0 included between the line of action of the force and a normal to the surfaces in contact does not exceed a certain value which depends upon the nature of the surfaces. The resultant force R has the same magnitude and line of action as the force P. In Fig. 1, R is resolved into two components: a force N normal to the surfaces in contact and a force F_r parallel to the surfaces in contact. From the above statement it follows that

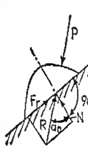

FIG. 1.

$$F_r \leq N \tan \alpha_0 \leq Nf_0$$

and the vertical component is 3,000 lb.

$$\Sigma x = 0 = s_{lk} + s_{bl} \times 19.2/20.8 + 1250$$
$$\Sigma y = 0 = s_{bl} \times 8/20.8 - 9500$$

From these equations, $s_{lk} = -24{,}050$ and $s_{bl} = 24{,}700$ tension.

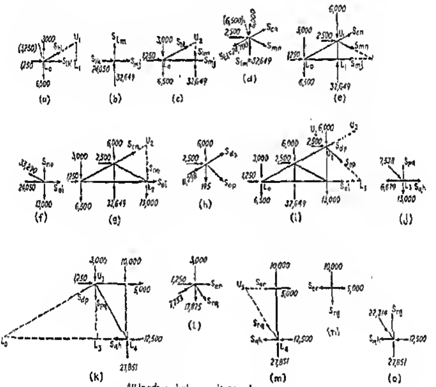
The minus sign indicates that the force in *lk* acts opposite to the assumed direction, *i.e.*, in compression.

Using the $\Sigma M = 0$ twice

ΣM about $U_1 = 0 = -s_{lk} \times 8 - 1250 \times 8 - 9500 \times 19.2$; from which $s_{lk} = -24{,}050$ or 24,050 compression

ΣM about $L_1 = 0 = s_{bl} \times 8/20.8 \times 19.2 - 9500 \times 19.2$; from which $s_{bl} = 24{,}700$ tension

The first method is frequently referred to as the "method of joints" and the second the "method of moments." Each method consists in applying the equations of statics



All loads and stresses in pounds

FIG. 2.

to a part of the truss cut from the whole in which the cut members are replaced by internal forces.

Stress in lm and mj. Sections 2-2. Isolate part below section [Fig. 2(*b*)]. Assume unknown forces as tension. s_{lk} was found to be compression, hence will act toward the pin.

$$\Sigma x = 0 = s_{mj} + 24{,}050; \text{ from which } s_{mj} = -24{,}050 \text{ or } 24{,}050 \text{ compression}$$
$$\Sigma y = 0 = s_{lm} + 32{,}649; \text{ from which } s_{lm} = -32{,}649 \text{ or } 32{,}649 \text{ compression}$$

If section 3-3 is taken, isolate part to left Fig. 2(*c*).

ΣM about $L_0 = 0 = s_{lm} \times 19.2 + 32{,}649 \times 19.2$; from which $s_{lm} = -32{,}649$ or 32,649 compression.

ΣM about $U_1 = 0 = -s_{mj} \times 8 - 1250 \times 8 - 9500 \times 19.2$; from which $s_{mj} = -24{,}050$ or 24,050 compression.

Stress in *bl* could also be found by ΣM about $L_1 = 0$.

Coefficients of Static Friction

Masonry and earth: dry masonry on brickwork, 0.6–0.7; timber on polished stone, 0.40; iron on stone, 0.3–0.7; masonry on dry clay, 0.51; masonry on moist clay, 0.33.
Earth on earth: dry sand, clay, mixed earth, 0.4–0.7; damp clay, 1.0; wet clay, 0.31; shingle and gravel, 0.8–1.1.

Natural cork: on cork, 0.59; on pine with grain, 0.49; on glass, 0.52; on dry steel, 0.45; on wet steel, 0.69; on hot steel, 0.64; on oiled steel, 0.45; water-soaked cork on steel, 0.56; oil-soaked cork on steel, 0.42.

Compound Sliding. A body sliding across another may be deflected crosswise from its original direction by a small force. This explains the ease with which an automobile may skid on the road or with which a plug gage can be inserted into a hole if it is rotated while being pushed in.

Coefficients of Sliding Friction for Special Cases

Soapy Wood. E. P. Lesley gives for wood on wood, copiously lubricated with tallow, stearine, and soft soap (as used in launching practice), a starting coefficient of

from which $s_{er} = 5{,}000$ tension and $s_{rq} = 22{,}314$ compression, or by taking section 13-13 and considering part to the right [Fig. 2(*m*)]

$$\Sigma M \text{ about } U_3 = 0 = s_{qh} \times 24 - (27{,}851 - 10{,}000)18 + 12{,}500 \times 24$$
$$\Sigma M \text{ about } L_4 = 0 = -s_{er} \times 24 + 5000 \times 24$$
$$\Sigma Y = 0 = s_{rq} \times 24/30 + 27{,}851 - 10{,}000$$

from which $s_{qh} = 888$ tension, $s_{er} = 5{,}000$ tension, and $s_{rq} = 22{,}314$ compression.

Stress in rg. Section 14-14. Consider the part around U_4 [Fig. 2(*n*)]

$$\Sigma x = 0 = -s_{er} + 5000 \text{ from which } s_{er} = 5000 \text{ tension}$$
$$\Sigma y = 0 = -s_{rg} - 10{,}000 \text{ from which } s_{rg} = -10{,}000 \text{ or } 10{,}000 \text{ compression}$$

or taking section 15-15 and considering the part around L_4 [Fig. 2(*o*)]

$$\Sigma x = 0 = -s_{gh} + 22{,}314 \times 18/30 - 12{,}500; \text{ from which } s_{gh} = 888 \text{ tension}$$
$$\Sigma y = 0 = s_{rg} - 22{,}314 \times 24/30 + 27{,}851; \text{ from which } s_{rg} = 10{,}000 \text{ compression}$$

Graphical Solution of Trusses

When the external forces acting upon a truss are all in the same plane and may be assumed to act at the joints of the structure, it is often convenient to make use of graphical constructions to determine the stresses in the members. A series of stress polygons may be constructed for the forces acting at the different joints, using the methods shown on p. 206, but a combination diagram, using what is known as "Bow's Notation," greatly simplifies the work.

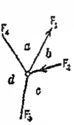

FIG. 3.

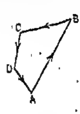

FIG. 4.

The forces F_1, F_2, F_3, and F_4 (Fig. 3) are all in the same plane and form a system in equilibrium. Their lines of action all pass through the same point (*o*). Letters are so placed as to bring each force between two letters, these letters being usually read in a right-handed or clockwise direction around the joint. F_1, F_2, F_3, and F_4 will then be designated *ab*, *bc*, *cd*, and *da*, respectively. A stress polygon (Fig. 4) is then drawn for the forces. Assume that the magnitudes, lines of action, and directions of F_1 and F_2 are known and that the lines of action only of F_3 and F_4 are known. The forces must be taken in order and the letters must be so placed that when the forces are read righthanded about the point *o* (Fig. 3) the sequence of the letters (in Fig. 4) will indicate the direction in which the forces act upon point *o*. The manner of using Bow's notation is illustrated by the following problem

Bow's Notation Applied to a Truss. The truss shown in Fig. 5 is loaded with a uniformly distributed dead load which may be considered to be concentrated at the joints as shown. First plot the polygon of external forces *ABCDEFGA* (Fig. 6). As the forces all act vertically, the sides of the polygon fall in the straight line *AF*. The supporting forces *GA* and *FG* are equal in this case, each being one-half the total load, so that no special construction for their determination is necessary. Start at any joint in the truss where there are not more than two unknown forces, *e.g.*, at the left end of the truss. The stress polygon for this joint is *ABHGA*. Reading the letters in a right-hand direction about the joint, the stress in the upper chord member is *BH*. This sequence of letters in the stress polygon indicates that this member acts downward and to the left on the joint, and therefore is in compression. The stress in the lower chord member is *HG*, and this sequence of letters indicates that this member acts to the right on the joint and therefore is in tension.

At the joint in the middle of the upper chord there are now two unknown stresses. Draw the stress polygon *HBCKH* for the second joint. The stress

Inflation pressure, lb per sq in.	Dry pavement		Wet pavement	
	Static, f_0	Sliding, f	Static, f_0	Sliding f
40	0.90	0.85	0.74	0.69
50	0.88	0.84	0.64	0.58
60	0.80	0.76	0.63	0.56

Tests of the Goodrich Company, on wet brick pavement, with balloon tires of different treads gave the following values of f.

	Coefficients of friction			
	Static (before slipping)		Sliding (after slipping)	
Speed, mph	5	30	5	30
Smooth tire	0.49	0.28	0.43	0.26
Circumferential grooves	0.58	0.42	0.52	0.36
Angular grooves at 60 deg	0.75	0.55	0.70	0.39
Angular grooves at 45 deg	0.77	0.55	0.68	0.44

Sleds. For **unshod wooden runners** on smooth wood or stone surfaces, $f = 0.07$ (0.15) when tallow (dry soap) is used as a lubricant (= 0.38 when not lubricated); on snow and ice, $f = 0.035$. For **runners with metal shoes** on snow and ice, $f = 0.02$. Rennie found for steel on ice, $f = 0.014$.

Rolling Friction

Rolling is substituted frequently for sliding friction, as in the case of wheels under vehicles, balls or rollers in bearings, rollers under skids when moving loads; frictional resistance to the rolling motion is substantially smaller than to sliding motion. The coefficient of rolling friction $f_r = P/L$ where L is the load and P is the frictional resistance.

Fig. 2.

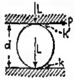

Fig. 3.

The frictional resistance P to the rolling of a cylinder under a load L applied at the center of the roller (Fig. 2) is inversely proportional to the radius r of the roller; $P = \frac{k}{r}L$. If r is in inches, values of k are as follows: hard wood on hard wood, 0.02; iron on iron, steel on steel, 0.002; hard polished steel on hard polished steel, 0.0002 to 0.0004.

Data on rolling friction are scarce. Noonan and Strange give for clean steel rollers on steel plates, for loads varying from light to those causing a permanent set, of the material, the following values of k: surfaces well-finished and clean; 0.0002 to 0.0005; surfaces well-oiled, 0.0005; surfaces covered with silt, 0.0015; surfaces rusty, 0.003.

When supporting forces are to be determined the loads *may* be concentrated at the lines of action of their resultants, but when internal stresses are to be determined the loads *must* be distributed at the various joints. Start with some joint of the truss where there are only two unknown forces and draw the stress diagram, Fig. 8. The magnitudes of the stresses in the different members are determined directly from the lengths of the corresponding lines and the scale used in the construction of the diagram. The nature of the stress (tension or compression) is determined by the use of Bow's notation.

A difficulty often arises that is illustrated by the truss of Fig. 7. It is impossible by the usual graphical procedure to complete the stress diagram, as it will be found that, after obtaining the stresses in the members meeting at the left end and at the next joint on both upper and lower chords, no joint with less than three unknown forces is available. To overcome this difficulty, some unknown stress may be calculated and placed on the diagram before proceeding with the graphical solution.

The stress which should be calculated in this case is that in the middle member of the lower chord. Taking moments about a point at the middle of the upper chord, $16RA = (14{,}733 \times 30) - (3200 \times 16) - [2720(22\frac{1}{2} + 15 + 7\frac{1}{2})] - (1360 \times 30) = 227{,}600 \therefore RA = 14{,}225$ (tension). Place this stress in the diagram and proceed.

The solution may be entirely graphical by noting that T must be on a line through E parallel to *et* and S must be on a line through f parallel to *fs* and also that TS must be parallel to *ts*. Hence the geometrical relationship may be indicated by any points T' and S' on the line through E and F as long as $T'S'$ is parallel to *ts*. Furthermore, TU must be parallel to *tu* and SR parallel to *sr*. If T' and S' are arbitrarily selected as shown in dotted lines, then U' is fixed. However U must lie on a line through V parallel to UV. All conditions can be fulfilled by moving the triangle $T'S'U'$ so that the sides move parallel until U' comes on the line through V parallel to *uv*. This point will then be U, and T and S will be determined.

Taper Keys. In Fig. 5 if the key be moved in the direction of the force P, the force H must be overcome. The supporting reactions K_1, K_2, and K_3 together with the required force P may be obtained by drawing the force polygon (Fig. 6). The friction angles of these faces are a_1, a_2, and a_3, respectively. In Fig. 6, draw AB parallel to H in Fig. 5, and lay it off to scale to represent H. From the point A, draw AC parallel to K_1, that is, making

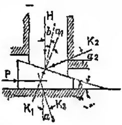

Fig. 5.

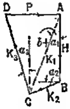

Fig. 6.

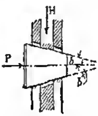

Fig. 7.

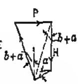

Fig. 8.

the angle $b + a_1$ with AB; from the other extremity of AB, draw BC parallel to K_2 in Fig. 5. AC and CB then give the magnitudes of K_1 and K_2, respectively. Now through C draw CD parallel to K_3 to its intersection with AD which has been drawn through A parallel to P. The magnitudes of K_3 and P are then given by the lengths of CD and DA.

By calculation, $K_1/H = \cos a_2/\cos (b + a_1 + a_2)$

$$P/K_1 = \sin (b + a_1 + a_3)/\cos a_3$$

$$P/H = \cos a_2 \sin (b + a_1 + a_3)/\cos a_3 \cos (b + a_1 + a_2)$$

If $a_1 = a_2 = a_3 = a$, then $P = H \tan (b + 2a)$, and efficiency $e = \tan b/\tan (b + 2a)$. Force required to loosen the key $= P_1 = H \tan (2a - b)$. In order for the key not to slide out when force P is removed, it is necessary that $b < (a_1 + a_3)$, or $b < 2a$.

The forces acting upon the taper key of Fig. 7 may be found in a similar way (see Fig. 8).

$$P = 2H \cos a \sin (b + a)/\cos (b + 2a)$$
$$P = 2H \tan (b + a)/[1 - \tan a \tan (b + a)]$$
$$= 2H \tan (b + a) \text{ approx.}$$

The force to loosen the key is $P_1 = 2H \tan (a - b)$ approx, and the efficiency $e = \tan b/\tan (b + a)$. The key will be self-locking when $b < a$, or, more generally, when $2b < (a_1 + a_3)$.

Screws

Screws with Square Threads (Fig. 9). Let r = mean radius of the thread $= \frac{1}{2}$ (radius at root + outside radius), and l = pitch (or lead of a single-threaded screw), both in inches; b = angle of inclination of thread to a plane at right angles to the axis of screw ($\tan b = l/2\pi r$); and f = coefficient of sliding friction $= \tan a$. Then, for a screw in uniform motion (friction of the root and outside surfaces being neglected) there is required a force P acting at right angles to the axis at the distance r. $P = L \tan (b \pm a) = L(l \pm 2\pi rf)/(2\pi r \mp fl)$, where the upper signs are for motion in a direction opposed to that of L and the lower for motion in the same direction as that of L. When $b \leq a$, the screw will not "overhaul" (or move under the action of the load L).

Fig. 9.

where $f_0 = \tan \alpha_0$ is called the **coefficient of friction of rest** (or of static friction) and α_0 is the **angle of friction of rest** (or angle of repose).

If the normal force N between the surfaces is kept constant, and the tangential force F_r is gradually increased, there will be no motion while $F_r < Nf_0$. A state of *impending motion* is reached when F_r nears the value of Nf_0. If one surface slides over the other, being pressed together by a normal force N, a frictional force F resisting the motion must be overcome. This force is usually smaller than F_r. The force F is commonly expressed as $F = fN$, where f is the **coefficient of sliding friction, or kinetic friction.** In the range of practical velocities of sliding, the coefficients of sliding friction are smaller than the coefficients of static friction. With small velocities of sliding and very clean surfaces, the two coefficients do not differ appreciably.

Under moderate pressures, the frictional force is proportional to the normal load on the rubbing surfaces. It is independent of the pressure per unit area of the surfaces. The coefficient of friction is approximately independent of the rubbing speed, when the speed is sufficiently low so as not to affect the temperature of the surface; at higher velocities, the coefficient of friction decreases as the velocity increases.

The coefficients of friction for dry surfaces (dry friction) depend on the materials sliding over each other and on the finished condition of the surfaces. With greasy (boundary) lubrication, the coefficients depend both on the materials of the surfaces and on the lubricants employed.

Data on the actual values of the coefficients of dry friction are not abundant, and those available depend on the conditions of the tests. Typical values of f and f_0 are given in Tables 1, 2, and 3. It has been generally observed that the sliding friction between harder materials is smaller than that between softer surfaces.

Table 1. Coefficients of Static and Sliding Friction
(Collected from various sources, mostly Morin)

Rubbing surfaces	Static: Dry	Static: Greasy	Sliding: Dry	Sliding: Greasy
Metals:

water-soaked	0.36			

Kingsbury, from tests on U. S. standard bolts, finds efficiencies for tightening up nuts from 0.06 to 0.12, depending upon the roughness of the contact surfaces and the character of the lubrication.

Toothed and Worm Gearing

The efficiency of **spur and bevel gearing** depends on the material and the workmanship of the gears, and on the lubricant employed. For high-speed gears of good quality the efficiency of the gear transmission is 99 percent, and with slow-speed gears of average workmanship the efficiency of 96 percent is common. On the average, efficiencies of 97 to 98 percent can be considered normal.

In helical gears, where considerable transverse sliding of the meshing teeth on each other takes place, the friction is much greater. If b and c are, respectively, the spiral angles of the teeth of the driving and driven helical gears (*i.e.*, the complements of their angles of inclination), $b + c$ is the shaft angle of the two gears, and $f = \tan a$ is the coefficient of sliding friction of the teeth, the efficiency of the gear transmission is $e = [\cos b \cos (c + a)]/[\cos c \cos (b - a)]$.

In the case of **worm gearing** when the shafts are normal to each other ($b + c = 90$), the efficiency is

$e = \tan c/\tan (c + a) = (1 - pf/2\pi r)/(1 + 2\pi rf/p)$, where c is the spiral angle of the worm wheel, or the lead angle of the worm; p the lead, or pitch of the worm thread; and r the mean radius of the worm. Typical values of f are as follows:

Rubbing speed of worm, fpm.	100	200	300	500	800	1200
Phosphor-bronze wheel, polished-steel worm	0.054	0.045	0.039	0.030	0.024	0.020
Single-threaded cast-iron worm and gear. . .	0.060	0.051	0.047	0.034	0.025	

Journals and Bearings

Friction of Journal Bearings. If P = total load on journal in lb, l = journal length in in., and $2r$ = journal diam in in., then $p = P/2rl$ = mean normal pressure, lb per sq in. of the projected area of the journal. Also, if f_1 be the coefficient of **journal friction**, the **moment of journal friction** for a cylindrical journal is $M = f_1Pr$ in.-lb. The work **expended in friction** at a speed of n rpm is $W_f = 2\pi Mn = 6.283f_1Prn$ in.-lb per min. For the **conical bearing** (Fig. 10) the mean radius $r_m = (r + R)/2$ is to be used.

FIG. 10.

Values of Coefficient of Friction. For very low velocities of rotation, (*e.g.*, below 10 rpm), high loads, and with good lubrication, the coefficient of friction approaches the value of greasy friction, 0.07 to 0.15. This is also the "pull out" coefficient of friction *on starting* the journal. With higher velocities, a fluid film is established between the journal and bearing, and the values of the coefficient of friction depend on the speed of rotation, the pressure on the bearing, and the viscosity of the oil. For journals running in complete bearing bushings, with a small clearance, *i.e.*, with the diameter of the bushing slightly larger than the diameter of the journal, the experimental data of McKee give an approximate value of the coefficient of friction (Fig. 11).

friction equal to 0.036, diminishing to an average value of 0.019 for the first 50 ft of motion of the ship. Rennie gives 0.0385 for wood on wood, lubricated with soft soap, under a load of 56 lb per sq in.

Asbestos-fabric Brake Material. The coefficient of sliding friction f of asbestos fabric against a cast-iron drum is 0.25 to 0.30 when at normal temperature. It drops rapidly with a rise of the brake temperature and is 0.16 to 0.20 at a temperature of 200 F. With a further increase in temperature, the value of f may show an increase caused by disruption of the brake surface.

Steel Tires on Steel Rails (Galton).

Speed mph	Start	6.8	13.5	27.3	40.9	54.4	60
Values of f	0.242	0.088	0.072	0.07	0.057	0.038	0.027

Railway Brake Shoes on Steel Tires. Galton and Westinghouse give, for cast-iron brakes, values for f, which decrease rapidly with the speed of the rim; the coefficient f decreases also with time, as the temperature of the shoe increases.

Speed, mph	10	20	30	40	50	60
f, when brakes were applied	0.32	0.21	0.18	0.13	0.10	0.06
f, after 5 sec	0.21	0.17	0.11	0.10	0.07	0.05
f, after 12 sec	....	0.13	0.10	0.08	0.06	0.05

Schmidt and Schrader confirm the marked decrease in the coefficient of friction with the increase of rim speed. They also show an irregular slight decrease in the value of f with higher shoe pressure on the wheel, but they did not find the drop in friction after a prolonged application of the brakes. Their observations give as follows:

Speed, mph	20	30	40	50	60
Coefficient of friction	0.25	0.23	0.19	0.17	0.16

Wood Brake Blocks. According to L. Klein, f is practically constant for velocities from 200 to 4,000 fpm and for pressures from 7 to 142 lb per sq in. The following values of f are for wood on lengthwise fiber brake blocks carefully machined:

	Beech	Oak	Poplar	Elm	Willow
Cast iron	0.29–0.37	0.30–0.34	0.35–0.40	0.36–0.37	0.46–0.47
Wrought iron	0.54	0.61–0.40	0.65–0.60	0.60–0.49	0.63–0.60

The higher values apply for cast iron when the brake wheel is cleaned with gasoline, the lower when it is only wiped clean; the reverse holds for wrought iron.

Hydraulic Hoists. According to H. Lang, for bronze or lignum vitae sliding surfaces on bronze, f is constant for slow reversing motion and for pressures of 30 to 1,500 lb per sq in. For surfaces continuously lubricated, $f = 0.08$; for surfaces wet with water through numerous slots, 0.10; for surfaces running dry and creaking, up to 0.30.

Stuffing boxes packed with hemp, cotton, or leather: f is constant for hydraulic pressures between 15 and 750 lb per sq in. For hemp or cotton packing, loose or woven, soaked in hot tallow, smooth rod, box not set up too tightly so that the packing is still elastic, usual dimensions—even after months of use, $f = 0.06$ to 0.11 (see also *Am. Mach.*, Feb. 3, 1898). When the packing is rendered difficult by unfavorable conditions, $f =$ up to 0.25. For well-made leather packing rings of soft leather $f = 0.03$ to 0.07; if of hard, stiff tanned leather, 0.10 to 0.13; under unfavorable conditions such as rough piston and dirty water, up to 0.20. The coefficient of friction is found to change inversely to the diameter of the cylinder; the depth of the leather does not influence the friction.

Grindstones. The coefficient of friction between coarse-grained sandstone and cast iron is $f = 0.21$ to 0.24; for steel, 0.29; for wrought iron, 0.41 to 0.46, according as the stone is freshly trued or dull; for fine-grained sandstone (wet grinding) $f = 0.72$ for cast iron, 0.94 for steel, and 1.0 for wrought iron.

Honda and Yamada give $f = 0.28$ to 0.50 for carbon steel on emery, depending on the roughness of the wheel.

Rubber Tires on Pavement. Arnoux gives $f = 0.67$ for dry macadam, 0.71 for dry asphalt, 0.81 for wet asphalt, and 0.17 to 0.06 for soft, slippery roads. For a cord tire on a sand-filled brick surface in fair condition, Agg (*Bull. 88, Iowa State College Engineering Experiment Station*, 1928) gives the following values of f depending on the inflation of the tire.

its action, and the equivalent lever is shorter with friction than without friction; the friction throws the line of action toward the center of rotation of link c.

Tension Elements

Frictional Resistance. In Fig. 15, let T_1 and T_2 be the tensions with which a rope, belt, chain, or brake band is strained over a drum, pulley, or sheave, and let the rope or belt be on the point of slipping from T_2 toward T_1 by reason of the difference of tension $T_1 - T_2$. Then $T_1 - T_2$ = circumferential force P transferred by friction must be equal to the frictional resistance W of the belt, rope, or band on the drum or pulley. Also, let a = angle subtending the arc of contact between the drum and tension element, measured in radians. Then, disregarding centrifugal forces,

FIG. 15.

$$T_1 = T_2 e^{fa} \text{ and } P = (e^{fa} - 1)T_1/e^{fa} = (e^{fa} - 1)T_2 = W$$

where e = base of the Napierian system of logarithms = 2.718+.

Table 4. Values of e^{fa}

$\frac{a°}{360°}$	f 0.1	0.15	0.2	0.25	0.3	0.35	0.4	0.45	0.5

$e^{\pi} = 23.1407$. $\log e^{\pi} = 1.3643764$.

f is the coefficient of friction of repose (f_0) when there is no slip of the belt or band on the drum and the coefficient of sliding friction (f) when slip takes place. In addition to the values given below, see p. 233.

Average values of f_0 for belts, ropes, and brake bands are as follows: For leather belt on slightly greasy wood pulley, 0.47. For leather belt on cast-iron pulley, very greasy, 0.12; slightly greasy, 0.28; moist, 0.38. For hemp rope on cast-iron drum, 0.25; on wooden drum, 0.40; on rough wood, 0.50; on polished wood, 0.33. For iron brake bands on cast-iron pulleys, 0.18.

Effect of Friction and Stiffness in Tension Elements. Let d = the rope diam, the diam of the chain stock, or the diam of the pin in link chains,

If a load L is moved on a roller (Fig. 3) and if k and k' are the respective coefficients of friction for the lower and upper surfaces, the frictional force $P = (k + k')L/d$.

Vehicles on Roads (wheels with iron tires). Values of $f_r = P/L$:

Smooth granite flags	0.006	Macadam, dust covered	0.028
Avg. street railway tracks	0.006–0.008	Poor stone pavement	0.033
Good asphalt	0.010	Macadam, mud covered, rutted	0.035
Very good stone pavement	0.015	Dirt road, very good	0.045
Macadam in best condition	0.010	Macadam of very poor quality	0.050
Good wood block pavement	0.018	Dirt roads, good to poor	0.08–0.16
Good stone pavement	0.020	Loose sand	0.15–0.30
Macadam in good condition	0.023		

For pneumatic rubber tires on smooth roads, f_r is 0.02 to 0.03.

FRICTION OF MACHINE ELEMENTS

Work of Friction—Efficiency. In a simple machine or assemblage of two elements, the work done by an applied force P acting through the distance s is measured by the product Ps. The useful work done is less, and is measured by the product Ll of the resistance L by the distance l through which it acts. The **efficiency** e of the machine is the ratio of the useful work performed to the total work received, or, $e = Ll/Ps$. The **work expended in friction** W_f is the difference between the total work received and the useful work, or $W_f = Ps - Ll$. The lost-work ratio $= V = W_f/Ll$, and $e = 1/(1 + V)$.

If a machine consist of a train of mechanisms having the respective efficiencies, $e_1, e_2, e_3 \ldots e_n$, the combined efficiency of the machine is equal to the product of these efficiencies.

Efficiencies of Machines and Machine Elements. The following values for machine elements are from "Elements of Machine Design," by Kimball and Barr. Those for machines are from Goodman's "Mechanics Applied to Engineering." The quantities given are percentage efficiencies.

Common bearing (singly)	96–98	Belting	96–98
Long lines of shafting	95	Pin-connected chains (bicycle)	95–97
Roller bearings	98	High-grade transmission chains	97–99
Ball bearings	99	Weston pulley block (½ ton)	30–47
Spur gear, including bearings:		Epicycloidal pulley block	40–45
Cast teeth	93	1 ton, steam hoist or windlass	50–70
Cut teeth	96	Hydraulic windlass	60–80
Bevel gear, including bearings:		Hydraulic jack	80–90
Cast teeth	92	Cranes (steam)	60–70
Cut teeth	95	Overhead traveling cranes	30–50
Worm gear: varies with thread angle	..	Locomotives (drawbar hp/ihp)	65–75

Wedges

Sliding in V Guides. If a wedge-shaped slide having an angle $2b$ is pressed into a V guide by a force P (Fig. 4) the force normal to the wedge faces will be $N = P/\sin b$, and the frictional force opposing motion along the axis of the wedge is $F = fN = fP/\sin b = f'P$, where $f' = f/\sin b$ is improperly called the coefficient of friction. In these formulas, the fact that the elasticity of the materials permits an advance of the wedge into the guide under the load P, has been neglected. If it be taken into account, then $F = fP$ $(\sin b + f \cos b)$. The common efficiency for V guides is $e = 0.88$ to 0.90.

FIG. 4.

HYDRAULICS

BY

E. W. SCHODER

REFERENCES: Daugherty, "Hydraulics," McGraw-Hill. Schoder and Dawson, "Hydraulics," McGraw-Hill. Harris, "Hydraulics," Wiley. Vennard, "Elementary Fluid Mechanics," Wiley. O'Brien and Hickox, "Applied Fluid Mechanics," McGraw-Hill. Report of Fluid Meters Committee, A.S.M.E.

General Properties of Liquids

A **liquid** is a substance that has a **definite volume**, but whose particles move relatively to each other so readily that, when unconfined laterally, the action of gravity causes it to flow and seek the lowest possible level. Hence a liquid **conforms to the shape of the containing vessel** or reservoir and, when at rest, presents a level upper surface unless restrained by the rigidity of the walls of a completely filled container.

Liquids and gases at rest may be regarded as having perfect fluidity. With **flowing fluids**, the existence of internal friction arising from viscosity must be considered and allowance must be made for its effects. Viscous resistance is a function of the time rate of internal slipping or distortion. True fluids have no rigidity or **form elasticity** but possess **bulk elasticity**.

Viscosity μ is the resistance offered by a fluid to relative motion of its parts. The absolute cgs unit of viscosity, the *poise*, is the resistance (in dynes per square centimeter of its surface) offered by a layer of the fluid to the motion, parallel to that layer, of another layer of the fluid at a distance of 1 cm from it, with a relative velocity of 1 cm per sec. The dimensions of the poise are (gm mass)/(sec)(cm) or (dynes)(sec)/(cm²). A customary unit is the **centipoise** (= poise/100), which happens to be the viscosity of water at 68.4 F. To convert centipoises into other units, multiply the centipoises by the following constants:

0.000672 for viscosity in (lb mass)/(sec)(ft) units
2.42 for viscosity in (lb mass)/(hr)(ft) units
3.60 for viscosity in (kg mass)/(hr)(m) units
5.60×10^{-5} for viscosity in (lb mass)/(sec)(in.) units
1.45×10^{-7} for viscosity in (lb force)(sec)/(in.²) units

Viscometers. Viscosity is measured by observing the time required for a certain volume of the liquid to flow, under stated conditions as to head, through a short tube of small bore. The **Saybolt Universal viscometer** has a vertical tube 0.483 ± 0.004 in. long and 0.0695 ± 0.0006 in. diam. For heavy oils the **Saybolt-Furol viscometer** is used; it differs from the Saybolt in having a tube diameter of 0.1240 ± 0.0008 in. The time of efflux of 60 cc in seconds is the viscosity in seconds Saybolt. The time of efflux of the Furol is approximately $1/10$ that of the Universal.

Viscosities of lubricants are measured at 100 and 210 F, of fuel oils at 77 and 122 F.

Kinematic viscosity ν is viscosity divided by mass density, or $\nu = \mu/\rho$. The unit in cgs units is called the **stoke**; a customary unit is the **centistoke** (= stoke/100).

The value of the kinematic viscosity [in (cm²)/(sec) units] can be obtained from the indications in seconds t of various viscometers by the following equations:

Saybolt Universal, when $32 < t < 100$, $\nu = 0.00226t - 1.95/t$
when $t > 100$, $\nu = 0.00220t - 1.35/t$

The efficiency for motion opposed to direction in which L acts $= e = \tan b/\tan (b + a)$; for motion in the same direction in which L acts, $e = \tan (b - a)/\tan b$.

The value of e is a maximum when $b = 45$ deg $- \frac{1}{2}a$; for example, $e_{max} = 0.81$ for $b = 42$ deg and $f = 0.1$. Since e increases rapidly for values of b up to 20 deg, this angle is generally not exceeded; for $b = 20$ deg, and $f_1 = 0.10$, $e = 0.74$. In presses, where the mechanical advantage is required to be great, b is taken down to 3 deg, for which value $e = 0.34$.

Kingsbury found for square-threaded screws running in loose-fitting nuts, the following coefficients of friction: lard oil, 0.09 to 0.25; heavy mineral oil, 0.11 to 0.19; heavy oil with graphite, 0.03 to 0.15.

Ham and Ryan give for screws the following values of coefficients of friction, with medium machine oil: High-grade materials and workmanship, 0.10; average quality materials and workmanship, 0.12; poor workmanship, 0.15.

The use of castor oil as a lubricant lowered f from 0.10 to 0.066.

The coefficients of friction of a **plain collar thrust bearing** used with a power screw, were: soft steel on cast iron, 0.12; hardened steel on cast iron, 0.09; soft steel on bronze, 0.08; hardened steel on bronze, 0.6.

The coefficients of static friction (at starting) were 30 percent higher.

Screws with V Threads. Let c = half the angle between the faces of a thread. Then, using the same notation as for square-threaded screws, for a screw in motion (neglecting friction of root and outside surfaces),

$$P = L(l \pm 2\pi rf \sec d)/(2\pi r \mp lf \sec d)$$

d is the angle between a plane normal to the axis of the screw through the point of the resultant thread friction, and a plane which is tangent to the surface of the thread at the same point (see Groat, *Proc. Engs. Soc. West, Penn*, vol. 34). Sec $d = \sec c\sqrt{1 - (\sin b \sin c)^2}$. For small values of b this reduces practically to $\sec d = \sec c$, and, for all cases the approximation, $P = L(l \pm 2\pi rf \sec c)/(2\pi r \mp lf \sec c)$ is within the limits of probable error in estimating values to be used for f.

The **efficiencies** are: $e = \tan b(1 - f \tan b \sec d)/(\tan b + f \sec d)$ for motion opposed to L, and $e = (\tan b - f \sec d)/\tan b(1 + f \tan b \sec d)$ for motion with L. If we let $\tan d' = f \sec d$, these equations reduce, respectively, to $e = \tan b/\tan (b + d')$, and $e = \tan (b - d')/\tan b$. Negative values in the latter case merely mean that the thread will not overhaul. Subtract the values from unity for actual efficiency considering the external moment and not the load L as being the driver. The efficiency of a V thread is lower than that of a square thread of the same helix angle, since $d' > a$.

For a **V-threaded screw and nut**, let r_1 = outside radius of thread, r_2 = radius at root of thread, $r = (r_1 + r_2)/2$, $\tan d' = f \sec d$, r_0 = mean radius of nut seat $= 1.5r$ (approx) and f' = coefficient of friction between nut and seat.

To tighten up the nut the turning moment required is $M = Pr + Lr_0f = Lr[\tan (d' + b) + 1.5f']$. **To loosen,** $M = Lr[\tan (d' - b) + 1.5f']$.

The total tension in a bolt due to tightening up with a moment M is $T = 2\pi M/(l + fl \sec b \sec d \operatorname{cosec} b + f'3\pi r)$. $T \div$ area at root gives unit pure tensile stress induced, S_t. There is also a unit torsional stress: $S_s = 2(M - 1.5rf'T)/\pi r_2^3$. The equivalent combined stress is[1] $S = 0.35S_t + 0.65\sqrt{S_t^2 + 4S_s^2}$.

position and the surfaces of division between the liquids are level. (But see below for capillarity, cohesion, adhesion, and surface tension as affecting glass-column gages.) In any continuous body of liquid at rest or moving at a uniform rate in a straight line the pressures at all points in a horizontal plane are equal.

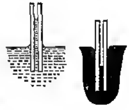
Compressibility and Elasticity of Liquids. A pressure of 1 lb per sq in. compresses liquids in volume as follows: Water, 1 part in about 300,000 (see p. 534); mercury, 1 part in about 4,700,000; ether, 1 part in about 120,000. For water in an iron pipe, this corresponds to a compression of 2 in. per mile length for a pressure of 10 lb per sq in. Because of this small compressibility, liquids are said to be practically incompressible. Liquids are perfectly elastic, *i.e.*, they quickly regain their former volume upon removal of the pressure. As a consequence of the small compressibility and decided elasticity of liquids, pressure waves, exactly analogous to sound waves in air, are transmitted through liquids with high velocities—for water, over 4 times as fast as sound in air.

Surface Tension. The surface between two immiscible fluids tends to assume the minimum area consistent with the volume of fluid enclosed and with the external forces acting on the fluids. Familiar illustrations are rain drops and soap bubbles, also bubbles of gas in a liquid. When one of the fluids is a gas, changes in its pressure and temperature usually cause little change in the interfacial tension, and consequently the latter is commonly treated as the surface tension of the liquid alone. Values of surface tension are given in Table 2.

Table 2. Surface Tension of Liquids in Contact with Air

Liquid	Temperature, deg F	Dynes per cm
Water	68	72.8
Mercury	59	487
Bisulphide of carbon	68	31.4
Chloroform	68	27.1
Ethyl alcohol (absolute)	77	22.0
Olive oil	68	34.7
Turpentine	70	28.5
Petroleum	68	25.9
Hydrochloric acid	68	66

Capillary Attraction. Cohesion, Adhesion, and Surface Tension. The exception to the otherwise general statement that the upper surface of a free body of liquid at rest is level, consists in the condition at the edges of the surface area, close to a bounding solid. If the liquid wets the solid (*e.g.*, water and clean glass), it is because there is a greater attraction between the liquid and the solid than between particles of the liquid, or adhesion is stronger than cohesion, and conditions are as shown by Fig. 1 (*a*). On the other hand, if the liquid does not wet the solid (*e.g.*, mercury and glass), cohesion is stronger than adhesion and conditions are as shown by (*b*) Fig. 1. The curved upper surface is called a **meniscus**.



(a) Water (b) Mercury

FIG. 1.—Capillary Attraction.

If small-bore glass tubes are used in gages, the effects of capillarity will cause water to stand higher and mercury lower than with large glass tubes, and even with the

If d_1 is the diameter of the bushing in inches, d the diameter of the journal in inches, then $(d_1 - d)$ is the diametral clearance and $m = (d_1 - d)/d$ is the clearance ratio. The diagram of McKee (Fig. 11) gives the coefficient of friction as a function of the characteristic number ZN/p, where N is the rpm, $p = P/dl$ the average pressure, lb per sq in., on the projected area of the bearing, where P is the load, lb; l the length of bushing, in.; Z the absolute viscosity of the oil in centipoises (see p. 244). Approximate values of Z at 100 (130) F are as follows: light machine oil, 30 (16); medium machine oil, 60 (25); medium-heavy machine oil, 120 (40); heavy machine oil, 160 (60).

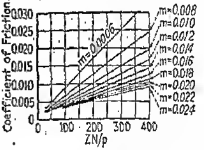


FIG. 11.—Coefficients of Friction of Journals.

For purposes of design of ordinary machinery with bearing pressures from 50 to 300 lb per sq in. and speeds of 100 to 3,000 rpm, values for the coefficient of journal friction can be taken from 0.008 to 0.020.

Thrust Bearings

Frictional Resistance. Step bearings or pivots may be used to resist the end thrust of shafts. Let L = total load, lb in the direction of the shaft axis; dA = an elementary area of the thrust-bearing surface, sq in.; y = distance of the area dA from its axis of revolution, in.; p = pressure on dA due to load L, lb per sq in.; and f = coefficient of sliding friction. Then, **moment of thrust friction** $= M = fp\int y\,dA$ in in.-lb; and the **work expended in friction** per min at n rpm. $= W_f = 2\pi Mn$ in in.-lb.

For a **ring-shaped flat step bearing** such as that shown in Fig. 12 (or a **collar bearing**), $M = \frac{1}{3}fL(D^3 - d^3)/(D^2 - d^2)$, where D and d are in in. For a **flat circular step bearing**, $d = 0$, and $M = \frac{1}{3}fLD$.

FIG. 12.

The value of the coefficient of sliding friction is 0.08 to 0.15 when the speed of rotation is very slow. At higher velocities when a collar or step bearing is used, f = 0.04 to 0.06. If the design provides for the formation of a load carrying oil film, as in the case of the Kingsbury thrust bearing, the coefficient of friction has values f = 0.001 to 0.0025.

Frictional Forces in Pin Joints of Mechanisms

In the absence of friction, or when the effect of friction is negligible, the force transmitted by the link b from the driver a to the driven link c (Figs. 13 and 14) acts through the center line OO of the pins connecting the link b with links a and c. With friction, this line of action shifts to the line AA, tangent to small circles of diameter d. The diameter d of the circle, called the **friction circle**, for each individual joint, is equal to fD, where D is the diameter of the pin and f is the coefficient of friction between the pin and the link. The choice of the proper disposition of the tangent AA with respect to the two friction circles is dictated by the consideration that friction always opposes the action of the linkage. The force F opposes the motion of a, therefore with friction it acts on a longer lever than without friction (Figs. 13 and 14). On the other hand, the force F drives the link c; friction hinders

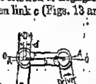

FIG. 13.

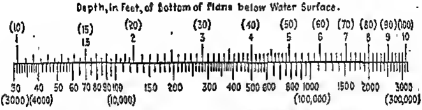
FIG. 14.

3. Liquid pressure is exerted with equal intensity in all directions.

4. **Liquid pressure acts perpendicularly to surfaces** in contact with the liquid. *For curved surfaces, the pressure at any point acts in the direction of the normal to the surface at that point.*

5. **The total liquid pressure against a submerged plane area** equals the product of the average intensity of pressure by the area, *i.e.*, the product of the intensity of pressure at the center of gravity of the area by the area,



Total Horizontal Pressure, in lbs., on Planes Extending from Water Surface to Depths Indicated on Upper Half of Scale.

FIG. 3.

or, as often stated, it equals the weight of a liquid column with a base equal to the area and height equal to the head on the center of gravity of the area. For a vertical rectangular plane extending to surface of liquid, with depth h and width b, the formula becomes: Total pressure $= P = \frac{1}{2}wbh^2$, where w is the weight of a unit volume of liquid. See **special calculating scale** for total pressures of water against vertical planes 1 ft wide and 1 to 100 ft deep (Fig. 3).

6. **The component in any direction** of the total liquid pressure on any submerged plane surface equals the product of the area of the projection of the surface on a plane perpendicular to the direction by the intensity of pressure at the center of gravity of the surface. For curved or non-planar surfaces, the principle may be applied to small portions of the surface, each regarded as plane, and the summation taken. Such cases, however, as **hollowed-out pump plungers and dished tank ends** have the same total pressures in the direction of the axis of the cylinder or tank as if the plunger or end were plane, *i.e.*, $P = Ap$, where A is the cross-sectional area of tank and p the average pressure. For submerged and floating bodies, see Buoyancy and Flotation, p. 249.

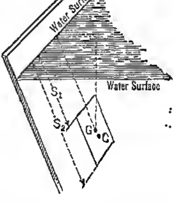


FIG. 4.

7. The **center of pressure** of a plane area subject to liquid pressure, *i.e.*, the point where the application of a single support will balance the liquid pressure, is located by the formula

$$e = \text{moment of inertia of area/area} \times x_{cg}$$

where e is the distance, in the plane, of the center of pressure below the center of gravity, x_{cg} is the distance from the water surface to the center of gravity of the area, and the moment of inertia is referred to the line where the plane cuts the water surface. In Fig. 4, the point G represents the center of gravity of the area and point C the center of pressure. C is always below G, but with relatively small areas submerged under large heads they are very close together and for most purposes may be considered coincident. For common shapes, calling the distance to the upper edge s_1 and to the lower edge s_2 (see Fig. 4), the values of e are

$$\text{Rectangle, } (s_2 - s_1)^2/12x_{cg}; \text{ Triangle, } (s_2 - s_1)^2/18x_{cg}; \text{ Circle, } d^2/16x_{cg}.$$

and R = the radius of the pitch circle in which the tension element travels, both in inches. The internal friction rigidity of the tension element causes a shortening at the driving end T_1 of the lever arm R an amount h_1 in inches, and at the following end a lengthening of the lever arm R an amount $= h_2$ in. Then, for simultaneous winding on and off, $T_1(R - h_1) = T_2(R + h_2)$. Approximately, $h_1 = h_2 = h$, whence $h_1 + h_2 = 2h$ (approx) and $T_1 = [1 + (2h/R)]T_2$.

This results in a frictional loss, and the efficiency of transmission is $e = 1 - (2h/R)$. If the tension element is only wound on the drum, $h_1 = 0$ and $T_1 = [1 + (h/R)]T_2$, with the corresponding efficiency $e = 1 - h/R$.

For **chains** the coefficient of friction between the link faces or pivots is $f = 0.2$ to 0.3; and when d = the diam of the link pin, $h = fd/2$.

For **hemp ropes,** $h = 0.03d^2$ to $0.09d^2$ according to the construction, material, and condition of the rope. In the absence of reliable values for wire ropes, those for chains may be tentatively used.

The **elastic rigidity** of the material is not a factor in simultaneous winding on and off, since the lever arm R is increased equally at the points of winding on and off; the work expended in bending the tension element as it is wound on is recovered as it straightens out in unwinding. But if there is only winding on, then the effect of the bending is to be taken into account.

Efficiency of rope and chain sheaves at low speeds, including journal friction (180 deg contact):

For fixed sheaves, chain, and wire rope, e = 0.94 to 0.96.
For floating sheaves, chain, and wire rope, e = 0.97.
Hemp rope sheaves:

Rope diam, in.	3/4	1	1 1/2	1 3/4	2
Fixed sheaves: e =	0.95–0.96	0.91–0.96	0.89–0.93	0.84–0.92	0.85–0.91
Floating sheaves: e =	0.97	0.96	0.95	0.94	0.93

For submerged bodies, the "weight in water" (or other liquid) $= (W - V_w)$, where V_w is the "loss of weight." The so-called "loss of weight" is not a real loss, but only apparent by reason of the buoyant force of the liquid. Thus, a block of granite weighing 170 lb per cu ft can be supported under water by an upward force of $(170 - 62.4) = 107.6$ lb per cu ft of granite. The difference, 62.4 lb per cu ft, is borne by the water, and whatever supports the water supports the difference also. Thus, when a ship moves into a drydock and displaces water from the dock, the bottom of the dock is not relieved of any weight at all.

The Hydrometer. A floating body rides higher in a heavy liquid than in a light one. The density and specific gravity, therefore, may be found by noting the depth to which a specially prepared float sinks. Such a device is called a **hydrometer.** The most common type is made of glass, consisting of a graduated stem above a hollow bulb, below *which is a smaller bulb containing mercury to make the whole instrument float upright.* By properly proportioning the weight and volume, any desired degree of sensitiveness may be obtained, subject to the increasing influence of surface tension on the stem as its size decreases. Hydrometers to suit various needs are obtainable in the market. The scale is graduated to read either specific gravity (referred to water) directly or according to some arbitrary scale. Of the latter the most widely used is the **Baumé scale** (see p. 86 for equivalents). **Twaddell's hydrometer** is used in England for liquids denser than water. See p. 85 for special hydrometer scales. Fahrenheit's and Nicholson's hydrometers are arranged so that weights may be added to sink them to a standard mark on the stem. For details, see textbooks on physics. For precise calculations, the temperature of the liquid should be measured and corrections made to the hydrometer indications. Nearly all liquids expand and contract much more than water for equal temperature changes near 60 F.

Determination of Specific Gravity and Volume of Solids by Immersion. By weighing an insoluble solid heavier than water in air and then in water, the specific gravity referred to water may be readily found, the specific gravity being (weight in air)/(loss of weight). Also, the volume of the solid = (loss of weight)/(weight of unit volume of water). The method is at once a convenient field method and one of precision when weights are accurately measured.

THE FLOW OF FLUIDS

General Considerations Regarding Flow

In the consideration of the flow of fluids, considerable advances are being made toward fuller logical interpretations of experimentally found facts and toward better guidance for future analytical and experimental undertakings.

Dimensional analysis (see p. 284) starts with the assumption that motion of a fluid may be influenced by any or all of a number of obvious variables such as the net force per unit area or pressure gradient p, the prevailing mean velocity V, and by the several properties of the fluid, such as weight per unit volume w, density or mass per unit volume $\rho(= w/g)$, viscosity μ, bulk modulus of elasticity e, surface tension σ; also by size, area, distances from and to boundaries, etc., expressible as several linear dimensions a, b, c, d. A grouping of terms embodying the essentials of the flow (but dimensionless and therefore of general application) can be written equal to a constant numerical factor times a (dimensionally independent) function of the dimensionless ratios d/a, d/b, d/c and of certain dimensionless groupings or numbers such as $Vd\rho/\mu$ and $V/\sqrt{dg}$. These last are known as the Reynolds and Froude numbers.

Saybolt Furol, when $25 < t < 40$,	$\nu = 0.0224t - 1.84/t$
when $t > 40$,	$\nu = 0.0216t - 0.60/t$
Redwood No. 1 (English), when $34 < t < 100$,	$\nu = 0.00260t - 1.79/t$
when $t > 100$	$\nu = 0.00247t - 0.50/t$
Redwood Admiralty (English),	$\nu = 0.027t - 20/t$
Engler (German),	$\nu = 0.00147t - 3.74/t$

For kinematic viscosity conversion table see p. 1905.

To convert kinematic viscosity to units of ft^2 per sec multiply by 1.075×10^{-3}. See also p. 1905.

Table 1. Viscosities of Fluids in Centipoises

Fluid	Temp, deg F	Viscosity	Fluid	Temp, deg F	Viscosity
Water	32	1.792	Spindle oil, sp gr = 0.885	60	45
	50	1.308		150	6.4
	68.4	1.000	Glycerin, 50% sol.	60	7.0

Sperm oil	60	42		150	70
	150	9.0			

Viscosity changes with temperature; for liquids it decreases as temperature increases, for gases it increases. Values of viscosity for various fluids at atmospheric pressure are given in Table 1. The viscosity of a gas does not vary with pressure for moderate ranges; for the "permanent" gases this is true up to 100 atmospheres.

The viscosity of glycerin and of castor oil is about 1,000 times, and that of machine oils 100 to 300 times, as great as that of water at ordinary room temperatures. The viscosity of oils changes much more with change of temperature than does the viscosity of water; water changes from 0.0179 poise at 32 to 0.0131 at 50 deg, 0.0100 at 68.4 deg, 0.0068 at 100 deg, and 0.0040 at 160 F.

The change in viscosity with temperature of typical American mineral lubricating oils is as follows:

Saybolt viscosity at 100 F	380	700	1,200	3,300	7,500
Saybolt viscosity at 212 F	68	90	120	210	300

Investigations published by the British Department of Scientific and Industrial Research show that the viscosity of water increases but slightly with increase of pressure; for animal and vegetable oils at 5,000 (10,000) [15,000] lb per sq in. pressure the percentage increase of viscosity is about 75 (200) [350] percent; for mineral oils at the same pressures the increase is 125 (550) [1,600] percent.

When two or more liquids that do not mix (*e.g.*, water, oil and mercury) are contained in the same vessel, the heaviest liquid occupies the lowest

such that $h = V^2/2g$ or $V = \sqrt{2gh}$; *i.e.*, the Pitot tube indicates the velocity head of the flowing water. If a tube of this sort is inserted in a pipe with water flowing under pressure, see Fig. 7, the water rises to a height h_v above the height in an open water column attached to a hole in the wall of the pipe; *i.e.*, the Pitot tube shows the sum of the pressure head and the velocity head of the water at the point of the tube, demonstrating that both sorts of head co-exist. The **Venturi meter** also illustrates the relation between pressure and velocity heads. This device (Fig. 8) consists of a conical nozzle-like reducer followed by a more gradual enlargement to the original size, which is that of the pipe line in which the meter is laid. At 1, 2, and 3 the pressure heads in the pipe are shown as they appear when measured by open liquid columns. Experiment shows that h_2 is less than h_1 by very nearly the difference in velocity heads $[(V_2^2/2g) - (V_1^2/2g)]$, and that at 3, where the mean

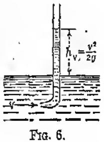

FIG. 6.

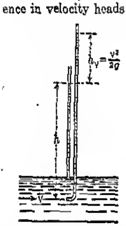

FIG. 7.—Pitot Tube.

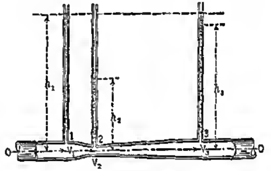

FIG. 8.—Venturi Meter.

velocity is again V_1, the pressure head is nearly h_1 again, the diminution being accounted for by loss due to friction of the flowing fluid. If the pressure in the pipe is changed, but the rate of flow kept the same, *e.g.*, by manipulating valves to the left of 1 and right of 3, all the pressure heads rise or fall equal amounts, *i.e.*, the **differences** in heads remain **unchanged**. If the pipe is not level, Fig. 9, allowance is made as follows: All points are referred to any convenient reference level, *O-O*. The difference in level of the tops of the open liquid columns is $H_1 - H_2 = (h_1 + Z_1) - (h_2 + Z_2)$, where Z_1 and Z_2 are the heights of 1 and 2 above the datum level, and are called the **potential** heads of these points. With no flow, liquid would stand at the same level in columns 1, 2, and 3, for both the level and sloping pipes. Hence the differences $h_1 - h_2$ in Fig. 8, and $H_1 - H_2$, in Fig. 9, are due solely to the flow of the fluid. It is to be noted that the difference in pressure heads of

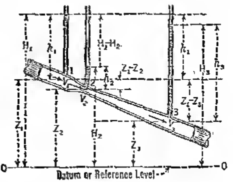

FIG. 9.

large tubes there is a curved surface where the liquid touches the glass. For water, the extra height is about $0.046/d$ in., where d is the internal diameter of the tube in inches. Thus, if a differential water-air gage (as in Fig. 7) has two glass columns nominally both ⅛ in. in internal diam, but actually one 0.01 in. larger and the other 0.01 in. smaller, the water will stand about $\frac{1}{16}$ in. higher in the smaller tube than in the larger, when a common hydrostatic pressure would lead one to expect them to stand at exactly the same level. In experimental work, this possible difficulty may usually be avoided by using larger glass tubes, say of ⅜ in. internal diam. **All readings should be taken at the level of the middle of the meniscus,** *i.e.*, the bottom of the curve for water and the top for mercury. These positions are away from the maximum effects of capillary attraction and are nearest to the proper level.

With many liquids such as water, ethyl alcohol, chloroform, benzene, turpentine, and olive oil the angle of contact between liquid and glass is 0 deg and in capillary tubes the meniscus is approximately hemispherical. In such a case the capillary rise = $2\gamma/(d_l - d_g)r$ where γ is the surface tension, d_l and d_g are the weight densities of the liquid and the gas (or vapor), and r is the internal radius of the capillary tube.

HYDROSTATICS

Pressure of a fluid usually means **intensity of pressure** above the local atmospheric pressure.

Gage pressure is the pressure indicated by a gage and shows pressure above the local atmospheric pressure. **Absolute pressure** commonly means **intensity of pressure referred to vacuum as zero.** Pressures less than the local atmospheric are always referred to by some distinct phrase, *e.g.*, "**10 lb suction,**" "20 in. (mercury) **vacuum,**" "5 lb per sq in. **absolute** pressure."

Pressure Head. Liquid pressure is often caused by the weight of the overlying liquid, and all liquid pressures can be thought of as being so caused. Special names are given to this real or imaginary height, as "**pressure head,**" "**static head,**" or, simply, "**head.**"

General Considerations Regarding Liquid Pressure

1. Pressure head is the height to the real or imaginary free liquid surface corresponding to the pressure of the liquid.

2. In any continuous body of liquid at rest, the **intensity of pressure** increases directly with the depth of the liquid. $p = hw$, or $h = p/w$, where p is the increase of pressure per unit area, h the increase of depth (or head), and w the weight per unit volume of the liquid. This law is true whether the liquid has a free upper surface open to the atmosphere or is confined and subjected to mechanical, gaseous, or other pressure.

For a liquid of sp gr s, $p = 62.4sh$ lb per sq ft $= 0.433sh$ lb per sq in. where h is the head, ft. Vacuum $= 1.13H/s$ ft $= 0.49H$ lb per sq in., where H is vacuum, in. of mercury.

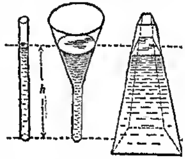

FIG. 2.

Hydrostatic Paradox. In the cases shown in Fig. 2, the intensity of pressure in pounds per square inch is the same at the bottoms of the variously shaped liquid containers. But the total liquid pressures against the various bottoms are proportional to the areas of the bottoms. The amount of liquid or its total weight makes no difference in either the intensity of pressure or the total pressure as long as the head h is the same. The fact that the total liquid pressure (bursting pressure) against the bottom may be many times greater or less than the total weight of the liquid is termed the **hydrostatic paradox.**

velocity of all the water flowing out, but to more than the average, *i.e.*, the actual discharge is less than that shown by the formula. (For theoretical principle, see Weirs, p. 259.) When the head above the center is equal to the vertical dimension of the orifice, the discharge is only about 1 per cent less, and when the head is twice the vertical dimension the diminution is

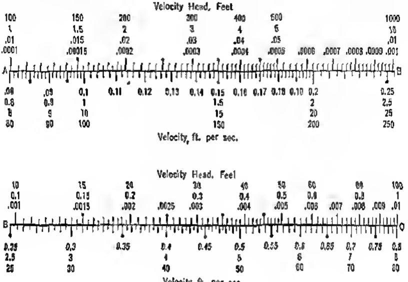

FIG. 11.—Velocity-velocity Head Conversion Scale.

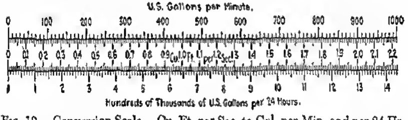

FIG. 12.—Conversion Scale. Cu. Ft. per Sec. to Gal. per Min. and per 24 Hr.

negligible, except for the most precise sort of investigations, for which a special calibration should be made to determine the exact coefficient. For lower heads, if h_c represents the head above the center and O the height of opening, Table 3 gives the percentage reduction in discharge and the corrected discharge coefficient for circular and rectangular orifices. The value

Table 3. Corrections for Rectangular and Circular Orifices

$\frac{h_c}{O}$	Rectangular Orifices: Reduction in discharge, percent	Rectangular Orifices: Corrected coefficient of discharge	$\frac{h_c}{O}$	Circular Orifices: Reduction in discharge, percent	Circular Orifices: Corrected coefficient of discharge
0.50	5.7	0.575	0.50	4.0	0.585
0.62	3.2	0.590	0.55	3.2	0.590
0.87	1.6	0.600	0.73	1.6	0.600
1.00	1.1	0.603	1.00	0.8	0.605

If the upper edge or top is at the surface, the distance of the center of pressure below the top is

Rectangle, $2s/3$; Triangle: vertex up, $3s/4$; vertex down, $s/2$; Circle, $5r/4$.

The maximum bending moment on a vertical rectangular beam subjected throughout its full length to liquid pressure, supported at top and bottom, and with the top support at the surface, occurs $0.09s$ above the center of pressure, or $\frac{1}{11}$ the span below the middle.

Example. Required the total pressure against a vertical gate 3 ft wide and 5 ft high at the bottom of a tank with water 12 ft deep; also the position of the center of pressure. The center of gravity of the gate face is $(7 + \frac{5}{2}) = 9\frac{1}{2}$ ft below the surface, and according to (5), total pressure against gate $= 9\frac{1}{2} \times 62.4 \times (5 \times 3) =$ 8,892, say, 8,900 lb. The total pressure scale (Fig. 3) gives 4,500 and 1,530 lb, respectively, for depths of 12 and 7 ft. The difference, 2,970 lb, is the pressure per foot of width, or 8,910 lb total. The center of pressure for the submerged rectangle is $(12 - 7)^2/12(7 + \frac{5}{2}) = 0.219$ ft below the cg, or 9.72 ft below the surface. Graphically, the center of pressure is the point where the area is cut by a normal through the center of gravity of the trapezoidal "pressure prism."

Buoyancy and Flotation. The total upward pressure of a liquid against a floating or a submerged body is the same as if the portion of the body below the surface were replaced by the liquid. In the latter case there would be simply a mass of liquid at rest, *i.e.*, with the net upward pressure from the surrounding liquid just **equal to the weight of the liquid** volume in question, which is the **volume displaced** by the floating or submerged body. Obviously, for a floating body, this weight and upward pressure equals the weight of the body. Hence, for any floating body, $P_u = W = Vw$, where P_u is the total upward pressure, W the weight of the body, V the volume of the displaced liquid (= "the displacement"), and w the weight of a unit volume of the liquid.

The draft or depth of flotation may be calculated when the weight, size, and shape of the floating body are known, for in all cases $W = Vw$.

Example. (Float control of a mechanism.) It is desired to obtain a force of 100 lb from a float when the water surface rises or falls 1 in. Required to find size of float necessary. From $P_u = Vw$, $100 = Vw =$ water-line area $\times \frac{1}{12} \times 62.4$, or area $=$ 19.25 sq ft, calling for, *e.g.*, a circular float 4.95 ft diam.

The center of buoyancy is at the center of gravity of the displaced volume of liquid. It shifts its position, both vertically and sidewise, as the floating body tips. The total upward pressure of the liquid may be regarded as concentrated through the center of buoyancy, about which it balances.

Stability, or tendency to float upright, demands that, when the floating body is tipped, the vertical through the new center of buoyancy shall pass the center line above the center of gravity of the body. The center line is the vertical line passing through the cg when the body is in equilibrium. When it does so pass, both the weight and buoyancy tend to right the floating body. When it passes below the center of gravity, both the weight and buoyancy act to overturn it. It is not necessary for stability that the center of gravity be below the center of buoyancy. In ships it is usually above. For submerged submarine boats, the center of gravity must be below the center of buoyancy for stability, because in this case the shape of the displaced volume of liquid does not change when the boat tips and consequently the center of buoyancy does not move relatively to the boat. The point where the vertical through the new center of buoyancy cuts the original vertical (now inclined), through the center of gravity, is called the **metacenter.** If, then, the metacenter is above the center of gravity, there is stability; if below, instability. The more it is above, the greater the stability.

suction and making the effective head greater than h. Values of the discharge coefficient as high as 1.55 have been found by experiment. For the downstream end of the tube, the coefficient is always less than 1. With high heads the jet may jump free and discharge as (*b*).

Rounding or beveling the sharp upstream edge, even slightly, increases the discharge of an orifice. Experiments at Cornell University on circular and square orifices, all free discharge, with various degrees of rounding of the upstream edge, show that the per cent increase in Q, over the sharp-edged Q, is 3.1 times the percent that the radius of the rounding is of the diameter of the orifice. This applies for roundings up to (but not beyond) 10 percent of the diameter of the orifice, where the increase is 31 percent, the coefficient being 0.80. Placing a sharp-edged orifice close to a side wall or a corner "suppresses" the contraction and increases the discharge. For each side of a rectangular orifice on which contraction is suppressed, the discharge is increased about 3 percent provided the side walls or the bottom do not extend beyond the plane of the orifice. If they do so extend, the coefficient remains the same as for fully contracted flow.

Attainable Precision in estimating the flow through a well-made sharp-edged or rounded-approach orifice depends on several factors. The orifice should be located at least 3 diameters away from any side wall and should be screened from the eddying effects of in-rushing water. If the head is low, guide vanes may be necessary to prevent whirlpools or vortices that obstruct the discharge. The size of the opening must be accurately measured. An error or uncertainty of a small percentage in the diameter makes twice that error in the discharging area; and a small percentage change in the head affects the discharge by half that percentage. **With accurate measurements** made with a knowledge of the various effects above mentioned, the engineer may feel assured that **the discharge will be within 3 percent of the calculated value.** By calibrating an orifice under the exact conditions of use, a future precision of 0.5 percent may be assured. Such an accuracy is seldom necessary except for precise testing or investigation. For an assured **precision within 1 percent**, maintenance of the orifice in "sharp-edge" condition is essential. A very slight dulling of the edge increases the discharge as much as 1 to 2 percent. As to the effects of a little corrosion, the nature and extent of the change in the coefficient depend on those of the defect. If a corroded edge is tuberculated, the discharge is decreased. If the rust accumulation is brushed or washed off, the effect is the same as dulling the edge. Published tables that give **coefficients to three places**, *e.g.*, 0.615, are deceptive, in that they suggest a precision of 1 in 600, when 1 in 60 would be nearer to the accuracy expected by an experienced engineer for routine cases.

Submergence, or Discharge under Water (*e.g.*, headgates). For openings in a "thin plate" or in a thin wall, the coefficients already given apply, but the value of h in the formula is the difference in water levels upstream and downstream from the opening. In the case of headgates there is liable to be uncertainty as to the effective area of the opening and of the amount of contraction. An uncertainty of from 5 to 10 percent is to be expected.

If the **submerged opening is in a thick wall**, even if the thickness is as slight as ½ the diameter of the orifice, the discharge is greater than for the opening in a thin wall. In this respect submerged discharge differs from discharge into the atmosphere, where the tube must be several diameters long before the coefficient increases. For a submerged tube 1 diameter long, square-edged entry, the discharge coefficient is about 0.76, as compared to 0.60 for the same tube with free discharge into the atmosphere. Rounding the entry further increases the discharge.

Investigations on **submerged square tubes** at the University of Wisconsin (*U. of W. Bull.* 216) and at Cornell University (*Eng. News.*, Nov. 2, 1916) show that the discharge coefficient under low heads becomes practically constant for a tube length greater than 1.5 diameters and that the value of the constant coefficient is a function of R/d, where R is the radius of the quad-

In practical application to particular cases of flow, one of these fluid properties is often dominant for a certain range of values of the pertinent dimensionless number, thus simplifying analytical treatment and study of experimental results. There should be recognition, however, of the existence of the other influences which may sometimes greatly affect the flow.

Steady, Unsteady, Uniform and Non-uniform Flows Defined. Flow is called **steady** when conditions in the stream (*i.e.*, in any cross-section of the flowing fluid) remain unchanged, especially the mass flowing per second, the mean velocity, and the size of the stream. If, also, the size and shape of the stream remain nearly constant from point to point along the course, the flow is called **uniform**. If the size of the stream and the velocity change from point to point along the course, even though the flow be steady, it is called **non-uniform**.

Examples of steady **uniform flow** are the common flows in pipes, hose, canals, and rivers. This sort of flow is seen to be associated with long conduits, and is controlled by the laws of fluid friction. **Pressure and head** are consumed (hence "lost") in forcing the fluid along against the resistances caused by the portions of the conduit in contact with the liquid.

Steady non-uniform flow is exemplified by the flow through orifices, nozzles, Venturi meters, revolving water turbines, weirs, etc. It is seen to be associated with cases of changing velocity, where flow starts from an early quiet body of fluid or where a flowing stream changes its size and its velocity. For these cases **pressure and head** are not consumed and lost (except to a small extent), but are **converted into moving energy**.

Unsteady flow proceeds in waves, pronounced pulsations or surges, or under rapidly changing conditions, *e.g.*, breaking ocean waves, pressure and velocity surges in a pipe line supplying a hydraulic ram, etc. No flow is steady or uniform when started. A short time elapses, of necessity, before steady conditions can be established. No ordinary flow is ever perfectly steady, there always being some pulsations and tremblings in velocity and pressure. The flow through a long pipe line carrying the discharge from a good double-acting plunger or piston pump with air chambers in good order is considered practically steady as far as flow calculations are concerned, although a pressure gage shows fluctuations of several percent.

Interrelations of Heads. Potential, Pressure and Velocity Heads. When water or any liquid of low viscosity spouts through an orifice in the side of a tank (Fig. 5), the jet has a velocity $V = \sqrt{2gh}$, nearly, where h is the head at the level of the orifice in the body of liquid well away from the orifice, and g is the acceleration constant of gravity. As a result of liquid friction at the orifice the actual velocity is 1 to 2 percent less than that given by the above formula. A jet issues in any direction according to the same law. If issuing nearly vertically, as in Fig. 5, the jet will rise nearly to the height of h ft above the orifice. For great heights the friction of the air and the breaking-up of the jet reduce the height considerably. See p. 274. For a fluid flowing with a velocity V, the name **velocity head** is given to the quantity $V^2/2g$, which corresponds to the static or pressure head h that could cause or could be caused by the velocity V.

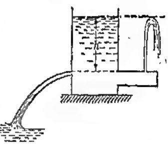

FIG. 5.

Figure 6 shows the water surface of an open stream flowing with velocity V, and against the current of which is directed the opening of a **Pitot tube**. The water rises in the tube to a height of h ft above the surface of the stream,

of the jet, the amount depending on the shape. A plain conical nozzle (called a **smooth nozzle**) causes no contraction. The velocity coefficient of a good nozzle is from 0.97 to 0.99, and this is also the discharge coefficient for smooth nozzles. A **square-ring nozzle** is really a sharp-edged orifice with high velocity of approach. The discharge coefficient depends on the proportion of the area taken up by the ring (see curve in Fig. 16, determined by J. R. Freeman from his experiments). The use of ring and undercut-ring nozzles arose from the mistaken notion that a better fire stream could be thrown from these than from a smooth nozzle. **Undercut-ring nozzles** have discharge coefficients of from 0.58 to 0.72, varying as for square-ring nozzles. The discharge coefficient of a well-finished **Doble needle nozzle** (Fig. 15) referred to the smallest area of passageway (surface of frustum of cone) between needle and nozzle proper, is from about 0.82 to 0.95, depending on the "opening" or position of the "needle." When nearly closed the coefficient is lowest; it is highest at about a ¾-open or full-load operating position, for which the curves are especially designed.

The nozzle formula is:

$$Q = CA_2\sqrt{\frac{1}{1-(A_2/A_1)^2}}\sqrt{2gh} = CA_2\sqrt{\frac{1}{1-(d_2/d_1)^4}}\sqrt{2gh}$$

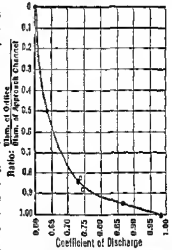

Fig. 16.—Discharge Coefficients for Square-ring Nozzles.

where A_1 and A_2 are the cross-sectional areas at the base of the nozzle (*i.e.*, where the pressure head is measured) and at the discharge tip, respectively, and d_1 and d_2 the corresponding diameters. C is the discharge coefficient and h is the pressure head in the pipe or hose just upstream from the convergence, referred to the level of the center of the discharge tip. (For ordinary purposes, h is usually measured by a spring steam-gage, or, more precisely, by an open water-column gage for low heads and a mercury gage for high heads. h is sometimes called the gage **pressure head**, and $[h + (V_1^2/2g)]$ the **theoretical or total head.**

For values of the **velocity-of-approach factor**, see p. 2008.

Range of Coefficients. Certainty. For water in smooth fire-hose nozzles, J. R. Freeman found an average coefficient of 0.977, with variations in averages for particular nozzles of 0.5 percent each way. The nozzles were attached to 2½ in. hose and had tip diameters of from ¾ to 1⅜ in. Several other experimenters have checked this value closely. For 1¾, 2 and 2½ in. tip diameters with convergence angles of from 10 to 15 deg, Mr. Freeman found an average coefficient of 0.995, with a variation (in averages for individual nozzles) of from 0.4 percent above to 0.8 percent below. The writer designed three nozzles for 4, 6 and 8 in. pipes, the tips being respectively 1.78, 2.74 and 3.57 in. in diameter; a common convergence angle of 25 deg was used, and all changes in direction were made by easy curves of 9 in. radius. The average discharge coefficient was found to be 0.986, with variations in averages within 0.3 percent and extreme variations in individual experiments (heads from 2 to 60 ft) of about 1 percent. **A coefficient of 0.98** may be considered reliable for good smooth nozzles within 1½ percent, without

the fluid in the pipe is $h_1 - h_2$ in both Figs. 8 and 9, but in Fig. 9 this difference is due partly to the hydrostatic effect of the difference of level. Consequently it is seen that a difference in pressure heads at two points along a stream (the velocity being different at these two points), may be due not only to a difference of velocity heads, but also in part to a difference in potential heads according to the hydrostatic law. Hence,

$$(h_1 + Z_1) - (h_2 + Z_2) = (V_2^2/2g) - (V_1^2/2g);$$
$$\text{that is, } h_1 + Z_1 + (V_1^2/2g) = h_2 + Z_2 + (V_2^2/2g)$$

This formula is the mathematical expression of **Bernoulli's Theorem.**

To summarize:

1. The total head present in a mass of flowing liquid is made up of potential head, pressure head and velocity head, mutually convertible, each into the other's form.

2. **Bernoulli's Theorem.** The total head in a particle of a continuous mass of flowing liquid at any one point in its stream line (*i.e.*, the path along which the liquid flows) is equal to the total head at any other position of its stream line, *provided* that there is no loss between the two positions due to friction, the giving up of work, etc., and no gain due to the application of outside work.

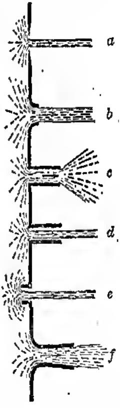

Fig. 10.—Types of Orifices.

Flow through Orifices

Flow of Liquids through Orifices. The general law of flow is $V = \sqrt{2gh}$, in which V is the velocity of the jet at its smallest section near or in the plane of the opening, h is the head referred to the level of the center of the stream cross section where the filaments of the issuing jet first become parallel.

The Standard Orifice for measuring or regulating purposes is the **sharp-edged orifice,** also called "orifice in thin plate." The jet contracts in size (Fig. 10*a*) just after coming through the opening of such an orifice. The area of the cross section of the jet, at a distance out from the opening about one-half its diameter, is about 0.62 of the area of the opening. The average velocity past this contracted section is about 0.98 to 0.99 of $\sqrt{2gh}$. Hence, calling A the area of the opening, the **discharge of a standard** sharp-edged orifice is $Q = 0.61A\sqrt{2gh}$, Q being in cu ft per sec when A is in sq ft, h in ft, and g in ft per sec per sec. The value of 0.62 is called the **contraction coefficient**; 0.98 to 0.99 is the **velocity coefficient,** and their product, or 0.61, is the **discharge coefficient.**

For Values of $\sqrt{2gh}$ for any head, see Velocity Head Scale, Fig. 11, also Conversion Scales (cu ft per sec to gal per min and per 24 hr), Fig. 12.

Example. For a circular sharp-edged orifice, 1 in. in diam, under 50 ft head, $Q = 0.189$ cu ft per sec = 85 gal per min.

Large Orifices with Low Heads, *e.g.*, sluice gates (see also Submergence). Unless the orifice is in a horizontal plane, *e.g.*, in the bottom of a tank, the top may be so much nearer the surface of the liquid than the bottom that the head at the level of center of orifice does not correspond to the real average

see under broad flat crests p. 263), and is frequently made of a steel plate or angle planed off and sometimes beveled on the downstream side to give a top flat portion from $\frac{1}{16}$ to $\frac{1}{8}$ in. wide.

Accuracy of Francis Formula. This formula is very widely used by engineers. It is reliable within from 1 to 3 percent for heads above 0.3 ft, provided that (1) the weir bulkhead has a vertical upstream face and occupies the full width of the channel, (2) the crest is level, (3) the channel of approach is deep (*i.e.*, the weir bulkhead is high, so that the velocity of approach is small—see below for corrections), (4) there is free access of the air to the space below the falling sheet of water (*i.e.*, between it and the downstream face of the weir), (5) the head is measured a distance upstream from

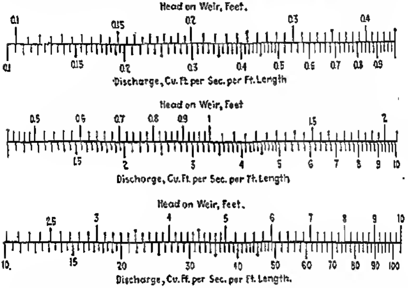

Fig. 17.—Weir Discharge Scale. Francis Formula, $Q = 3.33\,h^{3/2}$.

the weir of at least 4 times the head, (6) the side walls extend downstream from the weir (above the crest level) to prevent a lateral spreading as the water passes over the crest, and (7) due precautions in measuring are taken.

For very low heads, Francis formula results for discharge must be increased 1(3) percent when $h = 0.2$ ft, and 4(7) percent when $h = 0.1$ ft, the low values for a strictly sharp crest-piece with extremely smooth upstream face, the high values for ordinary iron plate with machine-planed top but somewhat corroded.

Effects of Errors or Uncertainties. A small percentage error in head causes $1\frac{1}{2}$ times that error in discharge. Conversely, the allowable percentage error in head is $\frac{2}{3}$ that in discharge. Considerable errors in the measured head may be made by careless methods of referencing the crest level to the head gage scale, and by assuming that a non-level crest is level without knowing the average level. The mean level of the water surface must be measured, not the crests of the small waves or surges existing in all flowing water. Rounding the upstream corner of the crest increases the discharge especially at low heads. Roughness of the upstream vertical face of the weir has the same effect.

For a **rectangular notch** with vertical sharp-edged ends, contraction occurs at the ends as well as at the crest, and the discharge is reduced approximately as though the length of the weir were decreased by $0.1h$ for each end contraction. Hence, the **Francis formula for a sharp-crested weir with**

of the coefficient, however, is not certain within from 1 to 3 percent without special calibration of the particular orifice.

Hamilton Smith's Coefficients. Relying chiefly on his own precise experiments of 1885 and earlier, and on those of Poncelet and Lesbros, 1827–1835, Smith published tables of coefficients for flow of water at ordinary low temperatures through sharp-edged orifices with square and round openings. Figure 13 shows the variation with head and diameter of these coefficients. Schoder has found corresponding variations with small circular sharp-edged orifices ½ to 1 in. in diameter. It will be noted that there is little change in the coefficient for heads above 2 ft and diameters greater than ½ in. Tests by Medaugh and Johnson (*Civil Eng.*, July, 1940) on very precisely made circular orifices agree with Smith within ½ of 1 percent.

Variously Shaped Orifices. Typical shapes are shown in Fig. 10. (*a*) is a sharp-edged orifice; (*b*) is a rounded-approach orifice; (*c*) is a short pipe or orifice in thick wall (length = 2.5 to 3 × diam), flowing full; (*d*) is a short pipe flowing like a sharp-edged orifice (see below); (*e*) is a re-entrant short pipe, or a Borda mouthpiece (when length < diam); (*f*) is a Venturi orifice.

For (*b*), when the curve is not too abrupt and there is a short length (= ¼ to ½ diam) of uniform bore where the jet issues, there is no contraction and the coefficients of discharge and of velocity are equal. The value for an average good, smooth, rounded orifice is 0.97; for the very best, 0.99; but with poor curvature, causing contraction and cross currents, the coefficient may be as low as 0.90.

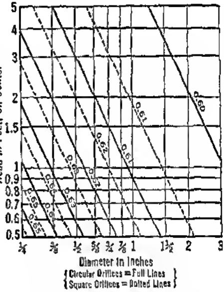

FIG. 13.—Coefficients for Sharp-edged Orifices. (Hamilton Smith.)

For (*c*), at low heads, the tube flows full at the downstream end and the discharge is "broomy," *i.e.*, agitated and divergent, while at high heads, above 40 to 50 ft, the jet jumps free at the upstream corner as from a sharp-edged orifice, as shown in Fig. 10(*d*). If the jet is once made to jump free by a high head, the head may be lowered to only a few times the orifice diameter without bringing back the "broomy" flow conditions. For "broomy" flow, the discharge coefficient is about 0.82; for clear flow it is 0.61, as for the sharp-edge. If the interior of the tube is greasy, the broomy flow will not occur, even at a low head. Obviously, this is an uncertain measuring device unless conditions are known.

For (*e*), when the length is 2.5 to 3 times the diameter, the above statements for (*c*) and (*d*) apply. The discharge coefficient is about 0.72 for "broomy" and 0.53 for clear discharge. For Borda's mouthpiece the coefficient is 0.53.

For (*f*), if the divergence angle is not greater than 7½ deg nor the length more than 10 nor less than 5 times the smallest diameter, the tube will flow full, and the velocity through the narrow "throat" will be greater than $\sqrt{2gh}$, because the pressure is less than atmospheric at that point, causing a

Narrow Rectangular and Trapezoidal Sharp-edged Notches with Crest Length Less than $2 \times h$. Experiments on narrow rectangular notches beyond the applicability of the Francis formula, covering heads up to 3 ft and widths down to 2.7 in., have shown that the formula $Q = 0.56(\frac{2}{3}lh\sqrt{2gh})$, *i.e.*, $Q = 3.00lh^{3/2}$, is reliable when h is as great as or greater than l. Hence for such cases we may take 90 percent of the discharge given by Fig. 17. For notches with l between h and $2h$ the coefficient increases and merges into values given by the Francis formula for two end contractions. For narrow trapezoidal notches the discharge may be expressed as the sum of that through a central rectangle and two triangles at the ends (see above formulas). A discharge coefficient of from 0.58 to 0.60 has been found to apply.

The inverted notch, with discharge proportional to head, allows very simple regulating and recording devices to be used with it. It is constructed with curved sides such that the width of notch above the straight level crest decreases just enough to keep the discharge proportional to the head. The rate of flow is given by the formula, $Q = C \times 1.57\sqrt{2g}(l\sqrt{h})h$, where Q is in cu ft per sec, l and h are notch width and head, respectively, in ft. With $C = 0.60$, this becomes $Q = 7.55(l\sqrt{h})h$. The product $l\sqrt{h}$ is constant, and this gives the relation for the curves of the sides. Starting with some desired or convenient head for a value of the discharge, say near the probable maximum to be expected, the value of the notch width at that height above the crest is calculated from the above formula for Q. These values of width and head give the constant value $l\sqrt{h}$. It is not necessary to continue the side curves of the notch closer to the crest than about $\frac{1}{32}$ to $\frac{1}{4}$ in. (depending on the range of heads); they may terminate in short verticals to the crest. The ratio of the discharge shut off by reason of such an abrupt termination of the curves to the full opening discharge (if it could be secured) is $0.64\sqrt{h_1/h}$, where h_1 is the height of the end verticals and h is the head of water. For values of $h/h_1 = 400, 100, 25$ and 10, respectively, the percentage reductions in discharge are 3, 6, 13 and 20. Unless the notch curves are accurately constructed, large errors in estimated discharge are to be expected. For results of tests see *Eng. News*, Nov. 25, 1915.

Velocity-of-approach effects, causing a greater discharge than from a deep quiet pool with the same head, have been variously expressed in the formulas adopted by different engineers. The Bazin and Rehbock formulas avoid the direct use of $v^2/2g$, where v is the mean velocity through the cross-section of the channel of approach upstream from the weir, where the head is measured. They provide for the changes in the discharge coefficient by expressions involving both the head and height of weir, but on the assumption that the distribution of velocities in the channel of approach is fairly uniform. The Fteley and Stearns and the Hamilton Smith formulas add $a(v^2/2g)$ to the observed (static) head, each using a constant value for a, (1.5 and $1\frac{1}{3}$ respectively, for weirs without end contractions), thus also assuming fixed natural velocity distribution, yet recognizing that the flow-assisting velocities near the surface of the channel of approach are usually greater than those near the bottom.

Recent experimental evidence favors the **Rehbock Formula** as probably the best of the rigid type of weir formulas for normal, or fairly uniform, velocity distribution in the upstream channel. This is for sharp-crested weirs without end contraction:

$$Q = \left(0.605 + \frac{1}{320h - 3} + \frac{0.08h}{d_0}\right)\frac{2}{3}Lh\sqrt{2gh}, \text{ (ft-sec units)},$$

$$= \left(3.234 + \frac{5.347}{320h - 3} + 0.428\frac{h}{d_0}\right)Lh^{3/2}$$

where d_0 is the height of weir or the depth of water at zero head. (See "Precise Weir Measurements" and discussions, *Trans. A.S.C.E.*, Vol. 93, 1929.) Although this is not strictly correct dimensionally, it gives values

rant rounding of the entry edges and d is the diameter of the orifice or the side of the square. Values of this constant are given below:

R/d, percent	33.3	16.7	8.3	6.2	4.2	3.1	2.1	1.0	0.0
Discharge coefficient	0.95	0.94	0.92	0.90	0.88	0.85	0.84	0.82	0.80

Several openings side by side (*e.g.*, headgates, intake screens, and baffles) cause an increase in the discharge, if submerged on the downstream side. For openings close together, increases of from 5 to 10 percent have been measured.

Velocity of Approach. If, upstream from the orifice, there is a high velocity of approach due to a small approach channel or passageway or due to peculiar flow conditions, the **velocity head**, $V^2/2g$, should be added to the static head to obtain h for the formula. The percentage effect is seldom large unless the channel is so small as to interfere with the flow by reducing contraction, etc., and then, of course, there will be considerable uncertainty. (See Nozzles, below.)

Pipe orifices (or orifice meters), *i.e.*, orifices in diaphragms inserted between pairs of flanges in straight portions of pipe lines, and **orifices in end-caps** on pipes, have been found to be reliable measuring devices. For a discussion of such orifices, see Head Meters, p. 1803.

The Miner's Inch. In some of the western states, water for mining and irrigation is sold by the **Miner's Inch**, which is the quantity of water that will flow through 1 sq in. of an opening in a plank under a head of (usually) 6 in. The arrangement of the opening (from 1 to 4 in. high), the thickness of the plank (from 1 to 3 in.), the datum

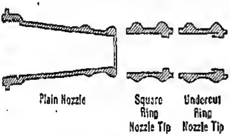

FIG. 14.—Types of Nozzles.

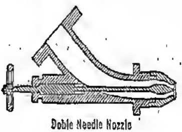

FIG. 15.

level for the measurement of the head (the top, center, or bottom of opening, as well as the head itself (from 3 to 9 in.), are largely matters of local custom and of state law. In Cal. and Mont., 40; in Colo., 38.4; and in Ariz., Idaho, Nev. and Utah, 50 miner's inches = 1 cu ft per sec. In some old deeds in the eastern states, water rights were sold by inches, but this commonly meant the discharge through 1 sq in. of some portion of an old-fashioned water wheel under the head at the particular power site, and, of course, is an extremely variable unit, the subject of many controversies in courts.

Oils, if not too tarry or viscous, and mercury have been found to have practically the same coefficients as water.

Time Required to Empty Tanks. An open tank whose cross-sectional area is uniform throughout its depth (*i.e.*, a vertical cylindrical or prismatic tank) will empty itself through an orifice, or a pipe (the discharge point being at the same level as the bottom of the tank), if there is no inflow, in just twice the time required to discharge the same amount of water under the initial head. For other shapes of reservoirs, the time may be computed by dividing the volume into five to ten horizontal layers and computing the time for each layer to discharge under the average head for that layer.

Nozzles. Figure 14 shows typical forms of nozzles. For **rounded-entrance flow nozzles** for the measurement of flow, see p. 1805. The **orifice formula**, modified to include velocity of approach, applies to the flow from nozzles. **Ring and needle nozzles** (Figs. 14 and 15) cause contraction

with the unsubmerged condition, until the downstream head, or backwater, is nearly one-half the upstream head above the crest. This is especially true for broad-crested dams, whether flat or rounded or with easy upstream sloping faces, since in these cases there is a considerable surface drop to the water and a decided increase in velocity even before the water leaves the crest. This condition remains practically unchanged with submergence until the downstream backwater head is over half the upstream head, *i.e.*, high enough to smother the flow.

For experimental results on weirs, see "Weir Experiments, Coefficients and Formulas," by R. E. Horton (U. S. Geol. Survey *W. S. & I. Paper* No. 200)

Flow of Fluids in Pipes

In any pipe or conduit through which a fluid is flowing, there is a continuous **loss of head** and of pressure. Figure 20 shows a portion of a pipe line through which fluid is being forced uphill from A toward B. With no flow, *i.e.*, only static fluid pressure, the head at B should be h ft less than at A. But, owing to the flow, there is loss of head along the pipe and the head at B is $(h + h_f)$ ft less than at A, where h_f designates the friction head between A and B. At the same time, the heads at both A and B are less than with the no-flow condition because of the loss of head upstream from A.

The loss of head or **friction head** depends on (1) the kind of fluid flowing, especially its viscosity; (2) the velocity of the fluid; (3) the size (*e.g.*, hydraulic radius) of the pipe or conduit; (4) the roughness of the interior surface; and (5) the length. Pressure has practically no effect on the loss of head because the viscosity of liquids and gases varies only slightly with pressure within the range ordinarily occurring in practice. The *pressure drop* due to friction $p_f = h_f/w$ depends on the density and therefore, for gases, on the pressure in the pipe.

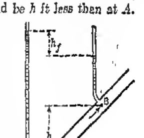

FIG. 20.

Viscous, Laminar, or Streamline Flow. A forced movement of fluid through a filled pipe is resisted by molecular forces at the inside wall, and slipping of the adjacent layers of fluid occurs, the result being a sort of telescopic sliding motion. If the rate of flow is not forced beyond the critical velocity, this viscous flow prevails throughout the entire cross section; in a circular pipe, the central core moves at twice the mean velocity. **Poiseuille's formula,** originally found experimentally in 1842 for capillary tubes, is now known to be applicable for the viscous flow of liquids and gases in all sizes of pipes. It is $h_f/L = 0.0326(\mu/s)(V/D^2)$, cgs units; where h_f is the loss of head in length L both in the same units; μ the viscosity, poises; s the specific gravity (weight, grams per cc); V the velocity, cm per sec; and D the diameter, cm. For V in fps and D in in., $h_f/L = 0.154(\mu/s)(V/D^2)$. For Q in cfs and D in in., $h_f/L = 28.3(\mu/s)(Q/D^4)$. The loss of pressure p in pounds per square inch per 1,000 ft of pipe is given by $p = 27.3\mu G/D^4$, where G is the flow, in U. S. gal per min; D the diameter, in.; and μ the viscosity, poises. Using B for barrels per hour (1 bbl = 42 U. S. gal), $p = 19.1\mu B/D^4$. The roughness of the pipe has practically no effect on true viscous flow except as the effective cross-sectional area may be less than for a clean pipe, and consequently a smaller value for D appropriate.

The Critical Velocity and Turbulent or Eddy Flow. When the rate of flow is forced beyond the critical velocity, turbulent or eddy flow sets in.

necessity of special tests. The writer tested, as a nozzle on a 6 in. W. I. pipe, a 6 × 3 in. rusted, riveted-steel reducer, 24 in. long, with projecting flat rivet heads at both ends and along a longitudinal seam. The discharge coefficient was 0.91 under heads of from 2 to 50 ft, allowance being made for rivet heads reducing the tip area. This may be taken as the low limit for an **extra rough conical nozzle.** In case of such a nozzle the coefficient 0.91 means that 17.2 percent of the head is "lost," *i.e.*, used up in overcoming friction.

The Venturi Meter. This device was invented by Clemens Herschel in 1887, and named after Venturi, who observed the principle in 1791. The general formula of this useful flow meter is discussed on p. 252. Referring to Fig. 9, the practical formula connecting the measured difference of pressure heads, $H_1 - H_2 = h$, with the mean velocity of flow in the throat is the same as the nozzle formula on p. 258. For coefficients, see p. 1806.

The nominal size of a Venturi meter is that of the pipe line in which it is to be placed. The throat diameter usually is made some size between 0.25 and 0.75 of the upstream diameter, depending on the rate of flow to be expected and on the pressure in the line. The throat velocity with the low rates of flow should be great enough so that the difference of pressure heads (often called the **Venturi difference**) will cause a measurable indication on the register or gage, but should not be so great as to cause the throat pressure to drop below atmospheric, lest there be trouble with air leaking into the gage and register connections. The upstream convergence angle of a Venturi meter may be from 25 to 30 deg, but the downstream divergence angle should not be greater than 7½ deg. The pressure connections usually are made to **ring piezometers**, consisting of circumferential passageways communicating to the interior of the meter by four or more small holes equally spaced around the pipe. The object is to assure the obtaining of the average pressure by avoiding dependence on a single piezometer hole subject to possible local disturbances. The ring piezometers are cast as part of the meter tube. The meters are usually made of cast iron and in several sections, bolted together. The throat is bronze-lined, very accurately bored to size and very smoothly finished. Venturi meters have been made of concrete and wood staves, the throats being lathe-finished bronze castings.

For the **loss of head** caused by the presence of a Venturi meter in a pipe line, see p. 1806.

Flow over Dams and Weirs

Weirs. A weir is a **bulkhead or dam** over which water flows, or a **notch** in the top of such a structure through which water flows. An orifice becomes a weir if the water surface upstream falls below its top edge. The velocity of approach is sometimes considerable, as for a low dam in a river at flood time, or it may be practically negligible, as for a small notch in the side of a large tank.

The theoretical discharge over a weir of width l is $Q = \frac{2}{3}lh\sqrt{2gh}$. This is two-thirds of the theoretical discharge through a rectangular orifice l ft long and h ft high under a head h. Actually, for a sharp-crested weir, contraction occurs at the crest. The under surface of the falling sheet of water rises as it leaves the sharp crest, just as for an orifice. The discharge coefficient is about 0.62, *i.e.*, $Q = 0.62(\frac{2}{3}lh\sqrt{2gh})$. This formula, for which the product of the constants = 3.33, may be expressed as $Q = 3.33lh^{3/2}$, and as such is known as the **Francis formula** for sharp-crested weirs. Q is in cubic foot per second and l and h are in feet. (See Weir Discharge Scale, Fig. 17.)

By a **sharp crest** is meant one with a sharp upstream corner from which the water springs. The crest itself may be of considerable thickness (but

(= cross-sectional area/wetted perimeter). In calculating the value of the Reynolds number, which is dimensionless, any consistent system of units

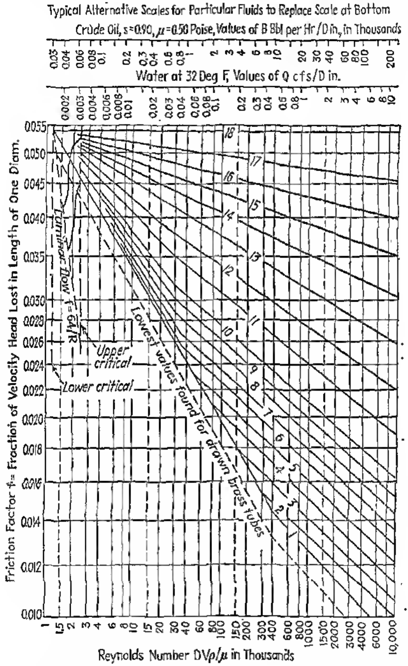

FIG. 21.—Friction Factors for Flow of Fluids in Pipes (to be used in conjunction with Table 4).

may be used. It is frequently convenient to use an equivalent of the Reynolds number R in which volume or mass flow replace velocity and in which

two end contractions is

$$Q = 3.33(l - 0.2h)h^{3/2}$$

This formula must not be used unless l is at least $2 \times h$.

See "Flow through Weir Notches [rectangular, triangular, Cipolletti, circular] with Thin Edges and Full Contractions," by V. M. Cone, *Journal of Agricultural Research*, U. S. Department of Agriculture, Vol. 5, No. 23 (1916); and a variety of weir-notch data by W. S. Pardoe in his discussion of "Precise Weir Measurements," *Trans. A.S.C.E.*, Vol. 93 (1929). See also Narrow Rectangular Notches, p. 262.

Cipolletti Trapezoidal Weir. Cipolletti found that a trapezoidal notch with end slopes 1 horizontal to 4 vertical (Fig. 18) just compensated for the reduction due to end contraction in a rectangular notch of the same crest length, and, accordingly, the simple Francis formula, $Q = 3.33lh^{3/2}$, may be used for such a trapezoidal notch. The crest length l must be at least $2 \times h$, and the crest should be 2 or $3 \times h$ above the bottom of the channel of approach to avoid a velocity-of-approach correction (see Narrow Trapezoidal Notches below). The Cipolletti weir has become popular in the western states for measuring irrigation water.

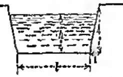

FIG. 18.—Cipolletti Weir.

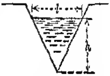

FIG. 19.—Triangular Notch Weir.

Triangular Notch. There are certain advantages in the triangular notch for measuring discharges that vary from a moderate maximum to a very small minimum, *e.g.*, 1 gal per min, and where about the same degree of precision is desired whether the discharge is high or low. The formula for a sharp-edged notch (Fig. 19) is $Q = C(\frac{4}{15}lh\sqrt{2gh})$, where l is the width of the notch a distance h above the vertex, and C is a coefficient with a value of from 0.58 to 0.59, based on experiments at Cornell University with heads up to 3 ft. and vertex angles of 28, 60, 90 and 120 deg. The average coefficient 0.58 was found for the 60 and 90 deg weirs, and 0.59 for the 28 and 120 deg weirs. These results are close to those of Cone (*loc. cit.*). Prof. Thomson found for 90 deg, 0.60, and for 127 deg, 0.62, heads 0.2 to 0.8 ft. Hence the discharge through a triangular notch $\left(\text{for which } l = 2h \tan \frac{\text{notch angle}}{2}\right)$ is from 38 to 40 percent of that given by the discharge scale (Fig. 17).

Very precise experiments on 90 deg V notches, with heads up to 10 in., have been made by James Barr (London *Engineering*, Apr. 8 and 15, and Oct. 28, 1910). With smooth upstream face and wide and deep tank, the coefficients at the same heads on several weirs were found constant within $\frac{1}{3}$ of 1 percent for heads ranging from 3 to 10 in., and within 1 percent for heads as low as $1\frac{1}{4}$ in. The tests show noticeable changes in discharge due to variations in roughness of upstream face of the notch plate. A surface like coarse emery increases the discharge over that for smooth brass some 2 percent (for a head of 0.3 ft). It was found also that the tank upstream from the notch should be seven to eight times the head in width and three to four times the head in depth below the vertex to avoid, respectively, increases and decreases up to 1 to 2 percent in discharge with narrow and shallow tanks. As above, $Q = C(\frac{4}{15}lh\sqrt{2gh})$. For a 90 deg notch $l = 2h$ and $Q = C(\frac{8}{15}\sqrt{2g})h^{5/2} = Kh^{5/2}$. With sharp-edged notches in smooth brass plates the formula $K = (0.2907 + 0.028/\sqrt{h})$, proposed by T. P. Strickland, applies. This is for Q in cu ft per min and h in in. For Q in cu ft per sec and h in ft, $K = (2.42 + 0.067/\sqrt{h})$ and $C = (0.565 + 0.016/\sqrt{h})$.

nolds number which may be calculated from any of the following expressions:

$$R = 77.4\frac{DV}{\nu} = 14{,}200\frac{Q}{\nu D} = 31.6\frac{G}{\nu D} = 22.2\frac{B}{\nu D} = 3.94\frac{(W/w)}{\nu D}$$

where ν is the kinematic viscosity ($= \mu/\rho$, where ρ is density, g per cc, or, very closely, $= \mu/s$), w the weight density, lb per cu ft, and the other quantities are in the units given above.

For non-circular conduits or passageways, substitute $4m$ for D in the expressions for the Reynolds number, where m is the hydraulic radius, in. (= cross-sectional area, sq in. divided by wetted perimeter, in.)

Examples. *Plain Pipe Problem.* A reservoir is to be supplied with cold water by a pump through a cast-iron pipe line 2,800 ft long containing several elbows, T's, etc, and making the total equivalent length (see p. 271) 3,000 ft. The difference of elevation is 100 ft, and the rate of pumping is to be 200 gpm. What size of pipe should be laid, and for what working pressure should the pump be specified? *Solution:* The pump must force water against a head of 100 ft plus the friction loss of head. The practical problem is to avoid either too small a pipe with its large friction head and costly operation or one too large with unjustifiable first cost in view of the saving of head. Using the formula for the discharge units given in p. 265, $h_f = fLG^2/32.1D^5 = (3000 \times 40{,}000/32.1)(f/D^5) = 3{,}740{,}000f/D^5$. For the value of f, from Fig. 21, first compute Reynolds number (see above). Assuming water at 32 F, $\mu = .0179$ poise. $R = 31.6\ G\rho/\mu D = 31.6 \times 200 \times 1/0.0179D = 353{,}000/D$. Approximate calculations suffice for the value of Reynolds number for different assumed diameters. Trying $D = 4$ in., $R = 353{,}000/4 \approx 90{,}000$, and Fig. 21 shows, for category D, line 7, $f \approx 0.024$. Then $h_f = 3{,}740{,}000 \times 0.024/1{,}024 = 88$ ft. A 5 in. pipe, with $f = 0.025$, gives $h_f = 30$ ft; a 6 in. pipe, $h_f = 12$ ft; an 8 in., 3 ft; a 10 in., 1 ft; a 12 in., 0.4 ft, etc. The heads against which the pump must operate would be, for the 4, 5, 6, 8, 10, and 12 in. pipes, respectively, 188, 130, 112, 103, 101, 100.4 ft. The choice would be, probably, between the 6 in. pipe with a total head of 112 ft and an 8 in. pipe with 103 ft. If there were likelihood of some increase in demand beyond the specified 200 gpm, the 8 in. pipe would be preferable.

To Find Frictional Loss of Pressure. It is required to pump 100 bbl per hr of an oil of 20 deg Baumé gravity and 250 sec Saybolt viscosity through a 3 in. pipe. What pump pressure per 1,000 ft of pipe must be provided? *Solution:* The specific gravity for 20 deg Baumé is 0.933, and by the formula on p. 244 the absolute viscosity is 0.51. Reynolds number (see above) $= 22.2 \times 200 \times 0.933/0.51 \times 3 = 2710$, for which $f = .045$ (from line 6, Fig. 21, and category B, Table 4). Then $p = 0.0065 \times 0.045 \times 1000 \times 0.933 \times 10{,}000/243 = 11.4$ lb per sq in per 1,000 ft, or 60 lb per mile. The actual inside diameter of standard weight 3 in. pipe is 3.07 in. In the above example the use of 3.07 instead of 3 in. changes the result to 10.2 lb per sq in. This emphasizes the effect of small changes in diameter (see Percentage Effects, p. 270), and indicates the undesirability of too precise computations in cases where there are likely to be deposits of paraffin or of asphalt on the inside of the pipe.

To Find Proper Diameter. In pumping 1,300 bbl per hr of an oil of sp gr 0.9 and absolute viscosity 0.7, what is the minimum diameter of pipe permissible, if a friction loss of pressure of 160 lb per sq in. per mile is not to be exceeded? *Solution:* In practice, one of the commercial sizes available must be chosen. Proceeding by trial, assume $D = 6$ in., making the value of $R = 22.2B\rho/\mu D = 22.2 \times 1300 \times 0.9/0.70 \times 6 = 6200$, for which curve 4 of Fig. 21 shows $f = 0.037$, making $p = 252$ lb per sq in. per mile. This is nearly 1.6 times the specified 160 lb, thus indicating that a larger pipe is needed. But a relatively small increase in diameter causes a large decrease in friction, since D^5 is involved. Trying 7 in., R is $6/7$ of the former value, 6,200, or 5,300, and $f = 0.038$, making $p = 120$ lb per sq in. per mile. This is smaller than the specified 160 lb, and hence a 7 in. pipe is amply large, but, being a size not in common use, it would probably be preferable to select an 8 in. pipe which demands only 65 lb per sq in. per mile.

If the oil were quite viscous, say 1620 sec, Saybolt Furol ($\mu = 34$), sp gr $= 0.97$ (= 14 deg Baumé), a much larger pipe would be needed. For 12 in. pipe, R is 63.6. This indicates viscous flow, for which (see p. 264), $p = 19.1\mu B/D^4$, or $160/5.28 =$

agreeing within less than 1 percent with experiments on weirs from 0.2 to 4 ft in height with heads from 0.1 to 2 ft subject to the ratio h/d_0 not exceeding 4. For any particular weir and head, the discharge by this formula may be found readily by multiplying the discharge read from Fig. 17 by the ratio of the parenthesis value to the 0.623 corresponding to the Francis formula (p. 259). Thus for a head of 1.605 ft on a weir 3 ft high the parenthesis value is $0.605 + .0020 + .0428 = 0.650$. This is 4.3 percent greater than 0.623, and the 6.77 cfs per ft read from Fig. 17 for the head 1.605 ft is to be increased by this percentage, making it 7.06 cfs per ft of weir crest. Rehbock has suggested a dimensionally correct formula yielding results approximating closely to those of the regular Rehbock formula, but not quite so close to experimental data, *viz.*

$$Q = L\left(3.218 + 0.445\frac{h}{d_0}\right)(h + 0.0041)^{3/2}$$

The added value, 0.0041 ft, is thought to be due to capillarity at the crest.

A more general formula providing precisely for a wide variety in distributions of velocity in the approach channel (*op. cit.*), is

$$Q = 3.33L\left[\left(h + \frac{v_a^2}{2g}\right)^{3/2} + \frac{h}{3.33}\frac{v_b^2}{2g}\right], \text{ or the practical equivalent}$$

$$Q = 3.33Lh^{3/2}\left[1 + \frac{3}{2}\frac{v_a^2}{2gh} + \frac{3}{8}\left(\frac{v_a^2}{2gh}\right)^2 + \frac{v_b^2}{6.66g\sqrt{h}}\right]$$

the value in brackets in the last formula being the multiplier for the discharge by the simple Francis formula (Fig. 17). Here v_a and v_b are, respectively, the mean velocities of approach above and below the crest level in the channel upstream from the weir, through the cross-section where h is measured. This formula can be used only when measurements have been made of not only the head but also the approach velocities, by current meter, Pitot tube, or floats, etc. For precision it is necessary to have certain knowledge of the upstream conditions.

Flow of water over dams varies from about 20 percent less to 20 percent more than for a sharp crest of the same length and with the same head. For **broad flat-crested dams,** the flat top wider than the head, the coefficient 2.64, instead of Francis's 3.33, applies, or, with sufficient accuracy, the discharge is 80 percent of that given by the Francis formula. If the upstream corner is rounded, the discharge may be greater. **Dams with steeply sloping upstream faces** (about 1 to 1) may have coefficients nearly as high as 4, as will also a **thin vertical bulkhead with a rounded upstream corner** (radius = 2 to 3 in. = thickness of bulkhead). **A very gradually sloping approach,** *e.g.*, 5 horizontal to 1 vertical, or a **rounding crest of large radius** introduces an appreciable friction effect, and the discharge may be no greater than for a sharp-crested weir. Non-vertical upstream faces on sharp-crested dams increase the discharge if inclined downstream and decrease it if inclined upstream, the coefficient being 3.10 for a 1 to 1 upstream and 3.73 for a 2 horiz to 1 vert downstream inclination, coefficients for intermediate inclinations being between these values. If **air is not allowed free access under the falling sheet** of water at the crest, the discharge over any **narrow-top** weir or dam is increased, but is also made less certain due to the tendency of the partial vacuum so formed to break at intervals and cause pulsating flow.

Submerged weirs and dams, where the water surface downstream from the dam is at a higher level than the crest, do not show much reduction in discharge, as compared

balance of discharges, as specified, might not result, but there would be valves in the pipes going to the reservoirs to adjust the discharges from time to time according to the needs, this being a matter for which the design of the pipe sizes, alone, does not provide. If it is desired to make the pipes in *A-B* and *B-C* of the same diameter, more loss of head must be allowed from *A* to *B*, say 8 ft. This gives about a 33 in. pipe for both *A-B* and *B-C* and a 15 in. pipe for *B-D*. If it is planned to limit the diameter for *B-D* to 12 in., the loss of head in *B-D* for this diameter and 5 cfs is first investigated. It is about 60 ft, and since there is only a total head of 30 ft available, a 12 in. pipe is not large enough.

Looping Pipe Problem. When a pipe branches into two or more pipes which again come together or are cross-connected (Fig. 23), the arrangement is known as a "loop." In such a case, there is the same total loss of head for each branch. For example, for fire-protection purposes it is desired to have available at *B* a supply of 2,500 gpm and 100 lb per sq in. hydrant pressure with the water flowing. What pressure must be maintained at *A* with this volume of flow and pressure at *B*? *Solution:* For a fixed h_f, common to the two branches, Q varies nearly as $\sqrt{D^5/L}$. Hence the ratio of the Q's is about $\sqrt{10^5/1000}/\sqrt{8^5/1800} \approx 2.35$. Dividing the 2,500 gpm into two parts, one 2.35 times the other, the 10 in. pipe has 1,755 and the 8 in. pipe 745 gpm. The friction head in each of the two branches is now calculated and compared for the necessary equality with the other branch. The formula is $h_f = fLG^2/32.1\ D^5$, with f corresponding (in Fig. 21) to $R = 31.6\,G\rho/\mu D = 310{,}000$ (for cold water) for the 10 in. and 132,000 for the 8 in. pipe. Figure 21, line 6, (category *D*) gives $f = 0.020$ and 0.022 for the 10 and 8 in. pipes, and the respective h_f values are $0.020 \times 1000 \times 1755^2/32.1 \times 10^5 = 19.2$ ft and $0.022 \times 1800 \times 745^2/32.1 \times 8^5 = 21$ ft. This is a fair check, and the loss of head, *A* to *B*, may be taken as 20 ft, or, say, 9 lb per sq in. drop in pressure, *i.e.*, the pressure at *A* must be 109 lb per sq in. If the whole discharge flowed through the 10 in. pipe alone, the loss of head would be 37 ft, or, 16 lb per sq in. drop in pressure. (For losses in elbows, T's, and hydrant and slight corrections to above, see p. 271.)

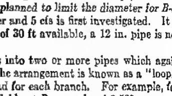

FIG. 23.

Useful Relations. From the formula $h_f = f(L/D)(V^2/2g)$, it is seen that h_f varies as $(L/D)V^2$ if f be assumed constant, which, for a moderate range of values, is approximately true. Introducing into this relation the discharge, $Q(=\pi D^2V/4)$, it is apparent that h_f varies as $(L/D^5)Q^2$. Also, Q varies as $D^{5/2}\sqrt{h_f/L}$, D varies as $Q^{2/5}/(h_f/L)^{1/5}$, and L varies as h_fD^5/Q^2. These relations enable one, at first trial, to make close estimates in cases where it is necessary to compare the (unknown) values of Q, h_f, D or L for two or more pipes in terms of the other (known or assumed) quantities.

Percentage effects due to a change, uncertainty, or error in any one factor: The above relations show that, for any pipe line under consideration, the other factors remaining the same, a small percentage change in available friction head causes ½ that percentage change in the discharge Q, or corresponds to ⅕ that percentage change in diam (in opposite way). A small change in Q corresponds to twice that percentage change in h_f, or ⅖ that in D; in D corresponds to 2½ times that percentage change in Q, or an opposite change of 5 times that percentage in h_f; in L corresponds to ⅕ that percentage change in D, or an opposite change of ½ that percentage in Q.

The considerable effect of small variations in diameter on the discharge and friction head are thus emphasized. To illustrate, if the diameters of two nominal 6 in. pipe lines are actually 5⅞ and 6⅛ in., a difference of 4 percent, the discharge of the latter, *with the same* h_f, *will be 10 percent more and the friction head, with the same* Q, *will* be 20 percent less than the former, due solely to the difference in diameters. If the smaller diameter is in whole or part the result of rusting, tuberculation, or incrustation, the increased roughness will still further decrease the discharge or increase the friction head if the same Q is forced through the pipe.

The loss of head along the pipe for such turbulent flow varies as $V^{1.75}$ for very smooth pipes at ordinary velocities and up to V^2 for quite rough pipes at ordinary velocities or for the smoothest pipes at velocities over 100 ft per sec; also it no longer varies inversely as the cross-sectional area, as for streamline flow, but more nearly inversely as the circumference (or the rubbing perimeter), actually as about $1/(\pi D)^{1.25 \text{ to } 1.16}$; also it now varies as a power of the viscosity much less than 1, probably about 0.25 to 0.15.

The formula $h_f = f(L/D)(V^2/2g)$ may be used generally for the turbulent flow of liquids and gases in long pipes. The friction factor f is a dimensionless number, L is the length of the pipe, D its diameter, V the mean velocity, and g the gravity acceleration. By extension, the same formula serves for *viscous* flow, when $f = 64/R$ and R is the Reynolds number. The values of f in Fig. 21 (a modification of Pigott's diagram) cover turbulent flow, and the formula is applicable to the flow of both liquids and gases in pipes. It may also be written

$$h_f = 6270fLQ^2/D^5 = fLG^2/32.1D^5 = fLB^2/65.6D^5,$$

where h_f and L are in the same units, D is in in., Q in cfs, G in U.S. gal per min, and B in bbl per hr. For other forms of this formula, see General Formulas for Flow of Fluids in Pipes, p. 267. For Flow of Gases see p. 272.

In arriving at a reasonably reliable formula for the ordinary pipes of engineering practice, there is considerable difficulty, chiefly for the following reasons: (1) There exists no standard of roughness; (2) the degree of roughness of a pipe's interior surface does not remain constant in service. The experimental data do not indicate precise coefficients but show a rather wide range of values from which the investigator must select limits and averages according to his judgment. (See Pigott, *Mech. Eng.*, Aug., 1933, and Kemler, *Trans. A.S.M.E.*, 55, 1933.)

In one case a few months' rusting of a 4 in. wrought-iron pipe increased the friction 20 percent. In another, incrustations due to 17 years' service increased the friction of a 48 in. cast-iron pipe 70 percent. An unlined linen hose causes over twice the resistance of a high-grade rubber-lined hose. One year's growth of slime in a large aqueduct increased the friction 20 percent. In these cases the discharges were reduced about half as much as the above-stated percentages for the same head.

Attainable Precision. A pipe, when new, may possibly discharge from 1 to 10 percent more or less than did some other pipe line apparently exactly like it. This difference in performance may be expected to change appreciably after water has been flowing and standing in the pipes for several months, and quite pronouncedly after several years, especially with different waters and in different climates. Nevertheless, data are available that serve to indicate approximately how much such service effects as "a slight layer of rust," "a thin deposit of lime," "a growth of slime," "considerable tuberculation," "heavy incrustation," etc., may be expected to reduce the discharge through a pipe line or increase the loss of head if the same discharge is maintained. The formulas and diagrams given herewith make due allowances for such of these effects as are stated with them.

Reynolds Number and Critical Velocity. Whether the flow in a certain pipe or other conduit is turbulent or viscous, i.e., whether it takes place above or below the critical velocity, is determined by the corresponding critical value of Reynolds number $VD\rho/\mu$, where V is the mean velocity, D the diameter, ρ the density (mass per unit volume), and μ the absolute viscosity of the fluid in the pipe. There is viscous or streamline flow if this number is less than about 2,000, or if $Q\rho/D\mu (= (W/w)\rho/D\mu)$ is less than about 1,570, where Q is the volume per second, W the total weight per second flowing, and w the weight per unit volume. For non-circular conduits or passageways, $4m$ is to be substituted for D, where m is the hydraulic radius

for a moderate range of diameters such as is found in any one class of work, *e.g.*, house-service pipes, street mains, power conduits. Actually, these resistances are not entirely concentrated in the fitting itself. They create a disturbed abnormal flow that does not return to normal until some distance downstream. The values given in Table 5 are for the total extra loss. The second column is based on $L/D = 40$ for $h_f = V^2/2g$ or, $f = 0.025$.

Problem of Short Pipe with Several Bends. A fairly smooth wrought-iron pipe line 150 ft long is to connect two tanks and must have a capacity of 15 cfs with a 20 ft head. There is a square-edged entry and there are four 90 deg short-turn elbows and two tees (with 90 deg deflections for the main line). What size pipe is proper? **Solution.** The total head is used up in supplying the loss at entry, the friction loss along the pipe, the losses in the elbows and tees, and finally the terminal velocity-head. (See Table 5.) Then $20 = (0.5 + f(L/D) + 4 \times 0.75 + 2 \times 1.50 + 1)V^2/2g$, or $20 = (7.5 + 150f/D)V^2/2g$. Figure 21 shows that f does not change much as D changes, since for a fixed Q the smaller D the larger is V. A value 0.017 seems to be about right for fairly smooth pipes from 12 to 20 in. with a velocity = about 10 fps. Substituting from $V = Q/A = Q/(\pi/4)D^2$, whence $V^2/2g = Q^2/[(\pi/4)^2 2gD^4]$, $20 = 42.4/D^4 + 14.4/D^5$. By trial, $D = 1.28$ ft, say 16 in. For this value of D, $V = Q/(\pi/4)D^2 = 11.6$ fps.

Flow of Gases in Long Pipes. For steady isothermal flow of nearly perfect gases through long pipes, three cases are readily distinguishable: (1) where the difference between the absolute pressures at the upstream and downstream ends of the pipe is small, say less than 10 or 15 percent; (2) where the difference is large but where the change in inertia due to change in velocity is negligible in comparison with the friction; (3) where both the difference between the end absolute pressures and the change in kinetic energy are relatively large.

For case (1), formulas of the type shown on p. 267 are applicable, $p_1 - p_2 = 2720fLsQ^2/D^5$, or $= fLW^2/(1.434D^5s)$. Here $p_1 - p_2$ is the drop in pressure in pounds per square inch between the upstream and downstream ends, Q and W are, respectively, the volume in cfs and the weight in pounds per second flowing; other symbols as on p. 267. For computing s (the specific gravity of the gas relative to water at max density), the mean of the terminal absolute pressures and temperatures may be used. For case (3), the formula is $p_1^2 - p_2^2 = \frac{W^2}{A^2 g}\frac{p_2}{w_2}\left[\frac{fL}{D} + 2\log_e\left(\frac{p_1}{p_2}\right)\right]$, and for case (2) the second term in the brackets may be omitted. For example, if the pipe is 5,000 diam long with $f = 0.020$, the first term $fL/D = 100$; and for $p_1/p_2 = 2$, the second term $2\log_e(p_1/p_2) = 1.39$ which is practically negligible in view of the magnitude of the first term and of the uncertainties in the proper value for f and other factors. But if $L/D = 1{,}000$ and $p_1/p_2 = 25$, the two terms become 20 and 6.44, and the latter cannot be ignored. For case (3), it may be expedient to neglect the second term for a first-trial solution. In place of the ratio p_1/p_2, the equal ratios w_2/w_1 or V_1/V_2 may be substituted because steady flow in a pipe of uniform diameter is assumed.

Flow of water in very small tubes is viscous flow. The formulas on p. 265, with values of f from Fig. 21 may be applied. For viscous flow of water in tubes 0.001 to 1 in. diam, the formula $V = 500(h_f/L)D^2(t + 10)/60$ gives close agreement with Poiseuille's formula between 40 and 100 F. Values of h_f and L must be in the same units, t in deg F; D in in., V in fps.

Flow of Light Crude Oils in Pipes. The resistance to the flow of oils lighter than about 30 deg Baumé (sp gr, 0.875) is not much different from that of water. The value 96 for C in the Chézy formula ($V = C\sqrt{mS}$, see p. 276) is sometimes used in designing

the units are not consistent. If Q is the volume flowing in cfs, s is the sp gr referred to water at max density, D is in in., G is U. S. gal per min, B is bbl per hr, W is weight flow, lb per hr, w is weight density, lb per cu ft, and μ is in poises, then the condition corresponding to the critical value $R = 2000$ is given by

$$Qs/D\mu = 0.141; \quad Gs/D\mu = 63; \quad Bs/D\mu = 90; \quad Ws/D\mu w = 508$$

These values indicate where the flow, if gradually decreased, ceases to be turbulent and true viscous flow begins. Turbulent flow may prevail with the value of $VD\rho/\mu$ as small as 1,200, and an intermediate or an alternating type of flow may occur under some conditions in a particular pipe for values between 1,500 and 3,000; in fact, under extraordinarily quiet conditions fully viscous flow may prevail for much higher Reynolds numbers.

General Formulas for Flow of Fluids in Pipes. If Δp is the pressure drop, lb per sq in., in a length of L ft of pipe of diam D in. discharging G g (U. S.) pm. or B bbl per hr or W lb per hr of a fluid of sp gr s referred to water at max density and of absolute viscosity μ poises, and if V is the mean velocity of flow in the pipe, fps, then the pipe formula may be written

$$\Delta p = \frac{0.081fLsV^2}{D} = 2720\frac{fLsQ^2}{D^5} = \frac{0.0134fLsG^2}{D^5} = \frac{0.0066fLsB^2}{D^5} = \frac{fLW^2}{1858 \times 10^4 D^5 s}$$

The value of f may be taken from Fig. 21 and Table 4 for a value of the Rey-

Table 4. Roughness Classification of Pipes by Material and Diameter, for Selection of Friction Factor f in Fig. 21

Such a stream (see Figs. 26 and 27) will be effective as a good fire stream for a height of 60 ft above the nozzle or for a horizontal distance of about 57 ft, the nozzle being pointed at angles above the horizontal of about 75 deg and 32 deg respectively, for farthest throw.

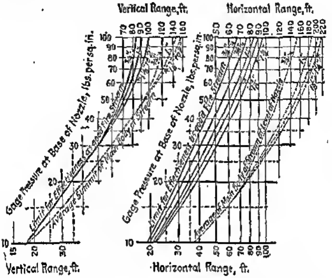

FIG. 27.—Vertical and Horizontal Ranges of Fire Streams.

Extra Losses of Pressure. With as many streams flowing as there are connections on the hydrant, the loss of pressure ranges from about 2 to 10 lb per sq in., but the total loss from street main to hose connection need not exceed 5 lb with ample-size waterways in the pipe connections and a well-designed hydrant. **Projecting washers** at the hose couplings cause an extra loss of head; *e.g.*, a single washer 3/16 in. thick with a hole 2.28 in. diam used in a 2½ in. hose was found to cause an average loss of 0.56 lb per sq in., and a 2 in. washer caused a loss of 3.11 lb per sq in., the rate of flow being 240 gpm or a velocity of about 16 fps. From this an idea may be gained of the resistance caused in small wrought-iron pipes by failure to remove inside burrs due to cutting off with wheel cutters. Failure to open fully hydrant valves causes much loss of pressure.

Practical Recommendations for Fire-protection Installations. Hydrants should be located at such intervals that not over 300 ft of hose need be laid in any one line, and so that about ten first-class fire streams can be concentrated on any large building. The drop will amount to 14 lb per sq in. for each 100 ft of the very best 2½ in. hose, and as high as 30 lb for a rough quality hose (when 240 gpm are flowing). A main pressure of 100 lb per sq in. during a fire is desirable, but, if the hose lines are rough and 500 ft long, fire protection cannot be assured unless a pressure of 200 lb is maintained at the hydrant. For important buildings the mains and laterals to hydrants should be at least 6 in. in diameter and as short as possible.

Water Hammer

Water hammer is the series of shocks, sounding like hammer blows, produced by suddenly checking the flow of water in a pipe. If a valve, turbine-gate, or faucet is suddenly closed, the kinetic energy of the arrested column of water is expended, if no relief devices are provided, in compressing the water and in stretching the pipe walls. Starting at the suddenly closed valve,

$19.1 \times 34 \times 1300/D^4$, whence $D = 12.9$ in. For a 14 in. pipe, $p = 116$ lb per sq in. per mile. As a check, $f = 64/R$ for viscous flow, and $p = 0.0066\, fLsB^2/D^5$.

To Find Discharging Capacity. For 15 miles between pumping stations with working pressures of 900 lb per sq in., what is the rate of flow for an 8 in. pipe, for an oil of specific gravity 0.92 and absolute viscosity 2.0? *Solution:* To get an approximate value for f, assume a value for B, say 1,000 bbl per hr, making $R = 1285$ and $f = 0.054$. Then $900 = 0.0066 \times 0.054 \times 79{,}200 \times 0.92B^2/8^5$, whence $B = 1{,}065$ bbl per hr. Checking back on R and f with this value of B, $R = 1{,}360$ and $f = 0.053$, close enough to the 0.054 used. Hence $B = 1{,}065$ bbl per hr may be taken as correct.

If the oil were very viscous, with $\mu = 40$ and $s = 0.96$, then an assumed 1,000 bbl per hr makes $R = 66.6$, indicating fully viscous flow. Then $900 = 13.1 \times 79.2 \times 40B/8^4$, whence $B = 610$ bbl per hr.

In cases of *turbulent flow*, when adjusting incorrectly assumed values of Q or D, it should be remembered that, for the same kind and length of pipe, p varies roughly as Q^2/D^5 (see Useful Relations, p. 270), or more exactly as $Q^{1.8}/D^{4.8}$ as an average for clean pipes.

Compound Pipe Problem. A pipe line is to be made up of stretches of several different diameters in series, the same Q flowing through all. Required to find the discharge Q for a given total loss of head. *Solution:* Apportion the head properly among the several pipes, and then check to find if the Q's are equal. Approximate results may be obtained quickly by noting that, for a fixed Q, h_f varies nearly as L/D^5, where L is the length of pipe of a certain diameter. Thus, if the total available friction head is 80 ft, and there are 3,000 ft of 12 in. and 2,000 ft of 8 in. pipe, the ratio of the two friction heads is $(3000/12^5)/(2000/8^5) = 0.198$, i.e., about $\frac{1}{5}$ as much loss of head in the 12 in. pipe as in the 8 in. pipe. Hence the available 80 ft for friction head is divided into 13.3 and 66.7 ft, or, per 1,000 ft, into 4.4 and 33.4 ft for the 12 and 8 in. pipes, respectively. With this apportionment of the friction head, the Q's are computed in turn for the 12 and 8 in. pipes, by the formula $h_f = 6270fLQ^2/D^5$, for Q in cfs. The value of f must correspond to the appropriate Reynolds number, $R = 14{,}200Q\rho/\mu D$. Not knowing Q in advance, a rough guess is made in order to get a first approximation to f, say $Q = 1$ cfs. Then R (for the particular fluid involved, *e.g.*, water at 32 F) $= 14{,}200 \times 1 \times 1/0.0179 \times 12 = 66{,}000$ for the 12 in. pipe. Figure 21 line 4, for category B, shows $f =$ about 0.022. Then $4.4 = 6270 \times 0.022 \times 1000 \times Q^2/12^5$, and $Q = 2.8$ cfs. Using this value in place of the assumed 1 cfs, $R = 185{,}000$. This changes f to 0.019, and Q becomes 3.0 cfs. For the 8 in. pipe $R = 300{,}000$, $f =$ about 0.018, and $33.4 = 6270 \times 0.018 \times 1000 \times Q^2/8^5$, or $Q = 3.1$ cfs, a fairly close check on the 3.0 cfs for the 12 in. pipe.

Branching Pipe Problem. It is sometimes necessary to design several branching pipes, fed by a single pipe, to discharge certain definite quantities. Such problems are usually solved by trial. Approximate results are readily obtainable in many cases by assuming a single value of f for all the pipes. The pressure head where the branching occurs is assumed (or else the loss of head to the branching), and the discharges for the several branches are calculated. The sum of these discharges must, of course, equal the discharge of the main pipe. If it does not, a second trial is made. In Fig. 22, the reservoir A is to supply reservoirs C and D, respectively, 10 and 30 ft lower than A.

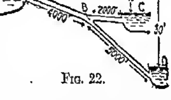

Fig. 22.

A-B = 4,000 ft, B-C = 2,000 ft, and B-D = 5,000 ft. (The nature of the problem is unchanged if A is a pump at a low elevation pumping into two reservoirs or into two districts.) What sizes of pipe are necessary to supply 20 cfs to C and 5 cfs to D? As a first trial, assume 5 ft loss from A to B, leaving 5 ft for B-C and 25 ft for B-D. The discharge Q for A-B is $20 + 5 = 25$ cfs. Now, guessing a medium $f = 0.020$, we have, for A-B, $5 = 6270 \times 0.020 \times 4000 \times 25^2/D^5$, whence $D \approx 36.5$ in. For B-C, $10 - 5 = 6270 \times 0.020 \times 2000 \times 20^2/D^5$, and $D \approx 29$ in. For B-D, $30 - 5 = 6270 \times 0.020 \times 5000 \times 5^2/D^5$, and $D \approx 14.5$ in. These approximate diameters may now be used to obtain practically correct values of Reynolds number and then f from Fig. 21, and the diameters are then recalculated. The nearest market sizes to these are the desired sizes. An exact

Relief Devices. Adequately proportioned air chambers on pumping mains and surge tanks on water-power supply pipes serve to absorb almost entirely the shock of water hammer. Means must be provided for replacing the compressed-air in the air chambers as this is soon absorbed by the water. Relief or safety valves with adjustable springs are not so good for water-hammer shocks, and are more likely to be out of order.

Flow in Open Channels

Flow of Water in Open Channels. Open channels may include canals, flumes, rivers, etc., and also any closed conduit, *e.g.*, a large pipe or a tunnel, when it flows only partly full. For open channels, instead of a loss of pressure head in a unit of length, its equivalent, or the surface slope or surface fall of the stream, is taken. The flow in an open channel, if long and of uniform cross-section, tends to adjust itself to a steady uniform flow, so that the surface is parallel to the bottom.

The Manning Formula. Because of the multitude of different shapes, the dimensions of the cross-section do not appear directly in the general formula, but indirectly in the **hydraulic radius**, or "hydraulic mean depth," m ($= A/w$ *i.e.*, cross-sectional area ÷ wetted perimeter). The Manning formula has been widely accepted, $V = 1.486m^{2/3}S^{1/2}/n$ (ft-sec), or $V = m^{2/3}S^{1/2}/n$ (metric). It is satisfactory for the steady uniform flow of water in open channels and is applicable also to pipes for the ordinary turbulent flow of water at usual low temperatures. Here V is the mean velocity, n the coefficient of roughness (practically equal to the old Kutter n, see Table 6), m the hydraulic radius, and S the hydraulic slope = surface fall/length. This may be regarded as a special form of the old **Chézy formula,** $V = C\sqrt{mS}$, with $C = 1.486m^{1/6}/n$. In terms of the pipe formula (see p. 265), Manning's $n = 0.0926\ m^{1/6}f^{1/2}$ (ft sec units).

Table 6. Values of Coefficient of Roughness, n, for Open Channels

Type of channel	n
ARTIFICIAL CHANNELS OF UNIFORM CROSS SECTION:	
Sides and bottom lined with well-planed timber evenly laid	0.009
Neat cement plaster, smoothest pipes	0.010
Cement plaster (3 cement to 1 sand), smooth iron pipes	0.011
Unplaned timber evenly laid, ordinary iron pipes	0.012
Ashlar masonry, best brickwork, well-laid new sewer pipe	0.013
(This last value should be used for the previous categories, if in doubt as to the excellence of construction and the maintenance free from slime, rust, or other growths and deposits.)	
Average brickwork, foul planks, foul iron pipes, ordinary sewer pipes after average uneven settlement and average fouling	0.015
Good rubble masonry, concrete laid in rough forms, poor brickwork; heavily incrusted iron pipes	0.017
CHANNELS SUBJECT TO NON-UNIFORMITY OF CROSS SECTION:	
Excellent clean canals in firm gravel, of fairly uniform section; rough rubble, "dry paving"	0.020
Ordinary earth canals and rivers in good order, free from large stones and heavy weeds	0.025
Canals and rivers with many stones and weeds	0.03–0.04

Degree of Roughness. Certainty. Open concrete, masonry, metal, or timber flumes can be cleaned periodically, and the removal of slime, weeds, silt deposits, etc., considerably increases their capacity. (See *Eng. News*, Aug. 29, 1912, p. 416.) For earth channels this is not readily done and for pipes it is more difficult and expensive—often impracticable. Open flumes are subject to rapid ice formation in winter in northern latitudes, to upstream retarding wind action, and to very rapid vegetable growth.

Siphons are arrangements of pipe or hose to cause liquids to flow from one level, *e.g.*, A in Fig. 24, to a lower level C, over an intermediate summit B. Before flow will start the pipe must be filled with the liquid, either by pumping from the end or by pouring in at the summit B. Valves are located, usually, at A and C. B cannot be more than 34 ft above A (at sea level) *less* the friction head from A to B *less* the velocity head in the pipe. With this limitation, calculations are made as for any pipe, the head being the difference in level between A and C. If the pressure at B is low, the dissolved air in the water is liberated and may accumulate in sufficient quantity to stop the flow, unless there is provision for removing it. A low summit, a high velocity and a small pipe tend to counteract the accumulation of air.

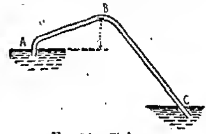

FIG. 24.—Siphon.

The loss of head due to curves, elbows, meters, etc., may be expressed either in terms of the velocity head of the flowing water or as equal to the loss in certain additional lengths of straight pipe. When these lengths are expressed in **pipe diameters** instead of in feet, it has been found that the value is nearly enough constant for a certain source of resistance so that a single average value may be used as sufficiently exact for designing purposes

Table 5. Loss of Head in Flow of Water through Elbows, Meters, Etc.
(Also expressed in equivalent lengths of straight pipe to cause equal loss)

Nature of resistance	Loss of head as a decimal or multiple of $V^2/2g$ (safe avg values)	Equivalent length of straight pipe expressed in pipe diameters

† Different makes of meters and different sizes of the same make vary considerably.

the path of the float is obtainable. By properly distributing floats across the stream, a fair estimate of the total discharge is obtainable if the width and depths have been accurately measured. The use of float measurements is commonly restricted to **surface floats** for rough approximations in reconnaissance, checking other measurements, and in times of high floods when there is too much ice or débris to allow the use of a current meter, and to **rod float measurements** in channels of fairly uniform depth where current meters or weirs are not available. For the surface floats any small pieces of wood will serve for one or two measurements. For more systematic work use $2 \times 2 \times 12$ in. wooden rods, weighted with iron or lead so they will float upright with an inch or so above water. Long rods reaching nearly to the bottom of the stream may be made in the same way, or 2 in. tin cylinders loaded with sand.

For surface floats the common assumption, if nothing is known as to the distribution of velocities from surface to bottom, is that the **mean velocity** is **about 0.8** *of the* **surface velocity**, *but there are frequent cases where the* mean velocity actually is from 90 to 95 percent of the surface, and occasionally the mean is greater than the surface. Hence, errors of 10 to 20 percent *are to be expected on a surface float measurement standing by itself. For long* rod floats, used in uniform-depth channels and adjusted to sink within a few inches of the bottom, careful work will give the discharge within 5 percent of the truth.

Current Meters. The best method of obtaining the discharge of a stream where no weir or dam exists and where the water cannot be measured by volume, is by using a current meter. This instrument is essentially a small wheel like a fan, propeller, or anemometer that revolves when held in flowing water, the speed of revolution depending on the velocity of the water. The meter is commonly calibrated by dragging through still water at different speeds, noting the time and distance for a whole number of revolutions indicated by a telephone receiver, a counter, or a chronograph. Current meters are variously arranged to be lowered into the water by cable, wire or rod. A "tail" like that of a weather vane serves to keep the wheel pointed against the current. When suspended from a wire or cable, a weight below the wheel assists in preventing the meter from being swept downstream. In deep and swift streams, or where the meter is held from high above the surface, a guy wire is used, extending upstream from just above the meter. When the meter *is attached to a rod,* the weight and tail are unnecessary. In order to hold the current meter in various parts of the cross-section of a stream, an overhead bridge, or a boat with anchors or guy lines, may be utilized. *(For stream gaging in winter, see Eng. News,* Sept. 12, 1912.)

Careful observations make it possible to determine the **discharge within 5 percent** if the location has been chosen where the currents are everywhere *fairly parallel to the banks, and if the bed of the stream is not too rough* with large boulders, or too indefinite because of soft mud, for accurate depth measurements as well as velocity determinations. **In canals,** with all conditions favorable, results **within 2 percent** of truth may be obtained by experienced observers.

The **Price current meter,** a cup-wheel meter with a vertical shaft (W. & L. E. Gurley, Troy, N. Y.) and the **Haskell current meter,** a propeller-type instrument having a horizontal shaft (E. S. Ritchie & Sons, Boston, Mass.), are arranged commonly so that the revolutions of the wheel operate a make-and-break in an electric circuit, indicating by a telephone receiver or by a counter register.

pipe lines for crude oil (42–43 deg Baumé, sp gr 0.814 to 0.809). One percent is added for each 3 deg Baumé, *i.e.*, lighter oils flow more easily. Diagrams based on the more practical form of the formula, *viz.*, $B = 1.125D^{2.5}\sqrt{p/L}$, are used, in which B is expressed in barrels (of 42 U. S. gal) per hour and D in inches; p is the necessary pump pressure in pounds per square inch and L the length of line in miles.

Fire Hose and Fire-extinguishing Streams. The roughest sort of hose is the unlined woven linen or cotton, and the smoothest is the heavy rubber-lined hose with the fabric interstices so well filled with rubber that the inside remains smooth even under high pressures. A poor grade of rubber lining or a poor fabric, or both, allows the rubber to be forced into the fabric, when under water pressure, and the interior of the hose may become nearly as rough as if there were no rubber lining at all. In purchasing what purports to be high-grade hose, it should be tested not only for strength to resist bursting but also for loss of head. The diagram in Fig. 25 shows the loss of pressure per 100 ft of length for various rates of flow in various grades of 2, $2\frac{1}{2}$ and 3 in. internal diameter hose. Figure 26 shows the discharge from various sizes of smooth nozzles for various pressures in the hose close to the nozzle. These diagrams are based on J. R. Freeman's experiments, *Trans. A.S.C.E.*, 1889. Figure 27 is a diagram showing the ranges, horizontal and vertical, of "good fire streams" and of "average of main body of stream," for various pressures in the hose line at nozzle. By a good fire stream is meant one that, at the range in question, has not broken into spray, and that projects about three-fourths of the water through a 10 in. circle and nine-tenths of it through a 15 in. circle. The "main body of stream" and the "extreme drops" carry much farther, but the water is too much spread out to be able to penetrate a hot fire and reach the burning materials before evaporating. A first-class fire stream is one from a nozzle of at least $1\frac{1}{8}$ in. tip diameter with at least 40 lb per sq in. pressure in the hose close to the nozzle. For $1\frac{1}{8}$ in. and 40 lb the discharge from a smooth nozzle is 240 gpm.

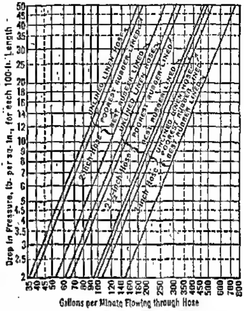

FIG. 25.—Loss of Pressure in 100 Ft. of Fire Hose at Various Rates of Flow.

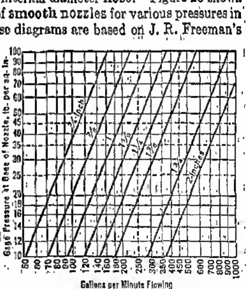

FIG. 26.—Discharge from Fire-hose Nozzles at Various Pressures.

opening projecting a little upstream from the body of the tube (see Fig. 36). The pressure holes in the pipe should be about 1 in. upstream from the impact point of the tube, so that the flow past them will be undisturbed by the presence of the tube in the pipe.

For abnormal flow in curved passages, or wherever a wall opening is subject to centrifugal action due to the flow not proceeding parallel to the wall, a two-opening tube is most convenient, as also where many tests in different pipes are to be made.

A sheath, or elongated stuffing box (Fig. 36), into which the point of the tube can be drawn back out of the pipe, is very convenient and is *practically essential for high pressures* where the flow in the pipe cannot be shut off. A corporation cock (½, ¾, 1 in. or larger, to suit the tube) may be permanently tapped into the pipe. The sheath should have a union coupling adapted for connection to the corporation cock. This gives a shut-off that allows a ready insertion of the tube at any future time. A ¼ in. tap and a gage cock are suitable for the pressure holes when a single-opening tube is used.

FIG. 34.

FIG. 35.

FIG. 36.

FIGS. 34–36.—Pitot Tubes for Insertion in Pipes.

The float gage *(Fig. 37) is used for determining* the level of a fluid surface and consists of a hollow float of noncorrodible metal or other substance, either spherical or cylindrical with convex or conical top and bottom. A light, rigid stem extends vertically upward, having an index mark that is guided along the edge of a graduated scale or is attached to an automatic recording mechanism. For cases of **great range of levels,** a graduated tape attached to the float and passing over a pulley or system of pulleys, and with a suitable counterweight, makes a sensitive indicator. The tape need be marked only every foot, if it passes the edge of a fixed auxiliary scale with subdivisions.

For precise work the float should be confined against lateral movement by a vertical pipe with internal diameter ¼ or ½ in. larger than the float. For the **greatest accuracy,** where errors of 0.001 to 0.004 ft are inadmissible, the float should be made at least *1 in. smaller than the pipe and should be loosely guided* (at the stem or by rounded radial fins on the float itself) to keep it away from the pipe so as to avoid **capillary lifting.** To lessen oscillations due to surges and waves, the lower end of the float pipe is capped and one or more small openings are made near the bottom to allow equalization of levels inside and outside. The area of the openings may be some 1 to 3 percent of the float-pipe section. For standing liquids in open tanks or reservoirs, the float pipe may be placed either inside or outside the container, as is most convenient. For flowing water in open channels it is placed outside the channel and communication is made by a small pipe, which must end perpendicularly to the inside wall of the channel and without projecting into the channel: *i.e.,* its end should be flush with the inside wall, so as to avoid suction effect (see Fig. 37).

Hook Gage, Point Gage, Plumb-bob Gage (Fig. 37). These are devices for locating the height of a liquid surface by observing its contact with the "point" attached to the movable graduated scale of the gage. The point gage has a sharpened point directed downward in place of the hook of the hook gage. For these gages the scale usually is engraved on a square brass rod. A steel or bronze tape is used for the **plumb-bob gage.** The

a wave of increased pressure is transmitted back through the pipe with constant velocity and intensity. The shock pressure is not concentrated at the valve, but if a bursting pressure is produced, it may show its effects near the valve simply because it acts there first. The velocity of the pressure wave for ordinary cast-iron pipe, 2 to 6 in. in diameter, is about 4,200 fps; for a 24 in. pipe it is about 3,300 fps; it depends on the elasticity of the metal and upon the ratio of its thickness to the diameter of the pipe. If the pipe were perfectly rigid the velocity would be that of sound through water, about 4,700 fps.

The increase of pressure is proportional to the destroyed velocity of flow and to the speed of propagation of the pressure wave. This increase is about 60 lb per sq in. for each ft per sec of extinguished velocity for 2 to 6 in. pipes, and about 45 lb per sq in. for each ft per sec for 24 in. cast-iron pipe. These increases of pressure will be attained only in case the valve is closed in less time than one round trip of the pressure wave.

When the pressure wave has travelled upstream to the end of the pipe where there is a reservoir or a larger main (the whole pipe then being under increased pressure with checked flow throughout), the elasticity of the compressed water and that of the distended pipe reverse the flow at that end of the pipe, and a wave of normal pressure (that of the reservoir or main) travels downstream, the flow being progressively reversed as the compressed water expands. When this wave of normal pressure reaches the valve, the kinetic energy of the column of water with reversed flow tends to create a vacuum at the valve. There the reversed flow is checked and the checking proceeds progressively upstream accompanied by a wave of subnormal pressure. When this wave reaches the upstream end (the whole pipe then being under subnormal pressure), the greater normal pressure in the reservoir or large main starts flow into the pipe, and a wave of normal pressure and forward flow travels downstream. When this wave reaches the valve there is forward flow throughout the pipe, the conditions being the same as when the valve was suddenly closed, and a wave of increased pressure and of checked flow again starts upstream. A complete cycle of pressure waves and reversals of flow occupies the time required for two round trips. The amplitude of the pressure vibrations becomes less with succeeding cycles because of friction, but the time interval remains constant.

If a high-pressure wave, in its travel through the pipe, enters a branch pipe with a closed, or "dead," end, there will be almost a doubling in the increase of pressure when the wave strikes the closed end. In some pipe systems dangerous water-hammer pressures are built up, for, if the back wave from a branch pipe with dead end has access to another branch the high pressure may receive further augmentation.

As the intensity of the excess pressure in the "hammer" wave depends on the amount of "extinguished" velocity, the same excess pressure is produced by suddenly reducing the velocity from 7 to 4 fps as by entirely stopping a velocity of 3 fps. If the flow is not checked rapidly, so that the wave from the first movement of the gate has time to travel upstream to the end and back again several times while the checking is in progress, the excess pressure is very much reduced. Hence, the wisdom of using slow-closing valves on long pipe lines. (See Relief Devices below.)

The excess pressure and the speed of the pressure waves are given by the formulas: $p = V\sqrt{Ew/g}$; $S = \sqrt{Eg/w}$, and also $p = V\sqrt{(w/g)\,(EE't)/(tE' + DE)}$; $S = \sqrt{(g/w)(EE't)/(tE' + DE)}$. [See Church's "Hydraulic Motors," Wiley, and *Proc. Am. Water Works Assn.*, 1904; also "Symposium on Water Hammer," 1933, Joint A.S.M.E. and A.S.C.E.] In these formulas p is the excess pressure intensity and S the speed of transmission of the pressure wave through the water in the pipe. The first two simpler formulas consider the pipe as perfectly inelastic. The last two formulas take into account the elasticity of the metal of the pipe. V is the extinguished velocity, fps, w the weight of 1 cu ft of water, $g = 32.2$, E the bulk modulus of elasticity of water = about 300,000 lb per sq in., E' the linear modulus of the pipe metal = about 30,000,000 lb per sq in. for steel, t the thickness of the pipe metal, and D internal diameter of the pipe. The same system of units should be used throughout. If the ft-lb sec system is used, the above values for E and E' must be multiplied by 144.

DIMENSIONAL ANALYSIS

BY

P. W. BRIDGMAN

REFERENCES: Bridgman, "Dimensional Analysis," Yale University Press. Campbell, "An Account of the Principles of Measurements and Calculation," Chap. XIII, Longmans.

Dimensional analysis is a method by which a partial knowledge of a physical situation may be capitalized and put into available form. The kind of partial knowledge necessary is a knowledge of the general nature of the fundamental equations which govern the system (that is, we must know whether the system is a mechanical, or electrical, or a thermodynamic system), and in addition, the nature of the boundary conditions which, together with the equations, determine the detailed solution in any special case. It is not required that the equations should be actually written out in detail; in fact the utility of the method is largely in its application to problems so complicated that the fundamental equations could not be actually written down, as, for example, in most practical problems of hydraulics.

The method depends on a property of all fundamental equations as ordinarily written, namely that the **form of such equations is independent of the size of the various units.** For example, the fundamental equation of mechanics, force = mass × acceleration, remains true no matter what the size of the units of mass, length, and time. It follows that any result that might be obtained by the solution of such equations must also be independent

Common Quantities and Their Dimensions

MECHANICAL QUANTITIES

Quantity	Dimension	Quantity	Dimension
Area	L^2	Moment of couple, Torque	ML^2T^{-2}
Volume	L^3	Work, energy	ML^2T^{-2}
Frequency	T^{-1}	Power	ML^2T^{-3}
Velocity	LT^{-1}	Action	$ML^{-2}T^{-1}$
Acceleration	LT^{-2}	Intensity of stress, Pressure	$ML^{-1}T^{-2}$
Density	ML^{-3}	Strain	0
Angle	0	Elastic modulus	$ML^{-1}T^{-2}$
Angular velocity	T^{-1}	Compressibility	$M^{-1}LT^2$
Angular acceleration	T^{-2}	Viscosity	$ML^{-1}T^{-1}$
Momentum	MLT^{-1}	Kinematic viscosity	L^2T^{-1}
Moment of momentum	ML^2T^{-1}	Capillary constant	MT^{-2}
Moment of inertia	ML^2		
Angular momentum	ML^2T^{-1}		
Force	MLT^{-2}		

THERMAL QUANTITIES

Quantity	Dimension	
Temperature	t	t
Quantity of heat	H	ML^2T^{-2}
Heat capacity, per unit volume	$Ht^{-1}L^{-3}$	$ML^{-1}T^{-2}t^{-1}$
Heat capacity, per unit mass	$Ht^{-1}M^{-1}$	$L^2T^{-2}t^{-1}$
Temperature gradient	tL^{-1}	tL^{-1}
Thermal conductivity	$HL^{-1}T^{-1}t^{-1}$	$MLT^{-3}t^{-1}$
Entropy	Ht^{-1}	$ML^2T^{-2}t^{-1}$
Enthalpy	H	ML^2T^{-2}

Two sets of dimensions are given for thermal quantities; the first set may be used in all problems in which *only phenomena of transfer enter, and the conversion of work into* heat does not play an essential part; the second set of dimensions must be used in connection with phenomena of conversion.

in many localities. These cause a rapid drop in discharging capacity, and should be allowed for by increased cross section or slope, or both. Channels in earth are also subject to loss of water by seepage, sometimes so considerable as to require special investigation. The state of uniformity of cross section is as important as mere local roughness. A channel with frequent minute changes of cross section must be regarded as a rough channel even if the sides and bottom are smooth in appearance. A circular section flowing only one-third or less full usually has a larger value of n than the same section flowing more than half full.

Erosion. All canals should be designed to have velocities high enough to prevent silt deposits and to retard vegetable growths. Earth channels, however, must not have such high velocities as to scour loose the material of the sides and bottom. Roughly approximate values of eroding velocities, in feet per second, are: for clay, ⅓; fine sand, ½; medium sand, 1; coarse sand and fine gravel, 2; gravel, 2 to 4.

Table 7. Values of the Hydraulic Radius, m, for Various Cross-sections

(m = cross-sectional area ÷ wetted perimeter)

Form of cross section	Value of m
Circle, flowing full, also half full	$d/4$
Square, no top (depth = width = d)	$d/3$
Half square (width = $2d$, depth = d)	$d/2$
Trapezoidal Channels (bottom width = b; depth = d):	
Half regular hexagon, side slopes 60 deg	$d/2$
Channel with 45 deg side slopes	$(bd + d^2)/(b + 2.83d)$
Channel with side slopes 1½ hor to 1 vert	$(bd + 1.5d^2)/(b + 3.61d)$
Channel with side slopes 2 hor to 1 vert	$(bd + 2d^2)/(b + 4.47d)$
Wide, shallow stream[1]	d (approx)

[1] Hence the term "hydraulic mean depth," sometimes used for m.

Open Channel Problem. It is necessary to carry 150 cu ft of water per sec in a rectangular unplaned timber flume whose width is to be twice the depth of water ($m = d/2$). What are the required dimensions for various slopes of the flume? *Solution:* For unplaned timber a value of $n = 0.013$ is safe. For assumed values of d = 3, 4, 5, and 6 ft, the cross-sectional areas of stream are 18, 32, 50 and 72 sq ft and the mean velocities for 150 cfs are 8.3, 4.7, 3.0 and 2.1 fps, respectively. By the Manning formula, reversed, $S = \dfrac{n^2}{2.208}\dfrac{V^2}{m^{4/3}}$ and, for the corresponding values of m, (1.5, 2, 2.5, and 3 ft) the slopes are found to be 3.1, 0.67, 0.20 and 0.077 ft per 1,000 ft, respectively, for the above assumed sizes. If it is required to find the dimensions of a canal with some desired depth or width for a given discharge and fixed slope, the procedure is to assume trial dimensions, calculate the mean velocity (= Q/area) and see if the value of m calculated by the Manning formula agrees closely with the m for the assumed dimensions. If not, new trials are made until there is close agreement. If the *shape* is fixed, *e.g.*, a semicircle or a 90 deg V flume, so that V = given Q ÷ (const × d^2), and m = const × d, the value of d may be calculated directly by the Manning formula.

Measurements of Flow in Open Channels. Where a weir or a dam does not exist, the velocity of flow is generally determined by the use of **floats** or by a **current meter** (See Hoyt and Grover, "River Discharge," Wiley). **Headgates and water wheels,** considered as orifices, are sometimes used, and are fairly accurate if calibrated for various gate openings by weir, floats or current meter. **Calculation based on open channel flow formulas is sometimes resorted to in cases such as extreme flood flows, where only high-water marks are left, in backwater problems, etc., this method being practically the only one available.**

Floats. By observing the time required for floating objects in a stream to pass over a measured distance, a good estimate of the velocity of the water in

of motion. There is obviously only one of these latter quantities, namely, g, the acceleration of gravity. From the detailed solution of the problem there should be found a connection between these quantities and the time of swing. The list of the variables and their dimensions is as shown in the table on page 282.

There are here 5 variables, expressed in terms of three fundamental units. Hence there are in general two independent dimensionless products. One of these is obviously w, the angle. The other is some product of powers of the remaining quantities. Values must be found of a, b, c, and d so that $l^a m^b g^c t^d$ is dimensionless. It is at once obvious that $b = 0$, because M enters only into m, and if b were not zero, there would be no way by which M could disappear from the product. It is also obvious that $a = -c$, in order that L should cancel, and $d = 2c = -2a$, in order that T should cancel. Hence the second dimensionless product is $(l/gt^2)^a$, or simply l/gt^2, since any power of a dimensionless quantity is itself dimensionless. Our general theorem now states that $f_1\{(l/gt^2), w\} =$ const., where f_1 is arbitrary. This relation may at once be put in another form, namely: $l/gt^2 = f_2(w)$; or finally, $t = \sqrt{l/g}\, f_3(w)$, where $f_3(w)$ is an arbitrary function of the angle. Dimensional analysis permits therefore the statement that the time of swing of a pendulum is independent of its mass, directly proportional to the square root of its length, and inversely proportional to the square root of gravity, but it does not give information about the way in which it depends on the angle. This latter information can only be obtained by actual detailed solution of the equation of motion (which is not here even written down); it is known that as a matter of fact $f_3(w)$ is approximately equal, for small angles, to π.

(2) *The problem of* **steady flow of liquid** *in a pipe of circular section under a pressure head.* The equations which govern are the equations of hydraulics; these equations contain the viscosity of the liquid, but not its density. The boundary conditions contain the diameter and length of the pipe and the difference of pressure between the two ends. From a complete solution of the problem the delivery through the pipe in unit time could be found, *and this would be expressed in terms of the quantities just mentioned.* The list of quantities and dimensions is:

Quantity	Symbol	Dimensions
Diameter of pipe	r	L
Length of pipe	l	L
Pressure difference	P	$ML^{-1}T^{-2}$
Viscosity	v	$ML^{-1}T^{-1}$
Delivery per unit time	D	L^3T^{-1}

Next, form the two dimensionless products. One of these is evidently r/l, and the second may be formed from r, P, v, and D, and is $r^aP^bv^cD^d$, or expressed in dimensional form, $L^a(ML^{-1}T^{-2})^b(ML^{-1}T^{-1})^c(L^3T^{-1})^d$. This must be dimensionless in L, M, and T, which gives the three equations:

$$\begin{aligned} a - b - c + 3d &= 0, \text{ condition on exponent of } L \\ b + c \phantom{{}+3d} &= 0, \text{ condition on exponent of } M \\ -2b - c - d &= 0, \text{ condition on exponent of } T \end{aligned}$$

The solution is: $d = -(a/3)$; $b = (a/3)$; $c = -(a/3)$, where a is arbitrary. Hence the dimensionless product is $(r^3Pv^{-1}D^{-1})^a$, or simply $r^3Pv^{-1}D^{-1}$.

Pressure Due to Deviated Flow

Force or Pressure Due to Deviated Flow. Pressure of a Stream against Stationary Solids. When a flowing liquid is turned from its course by a body such as a curved vane or a pipe bend, a pressure is exerted on that body. The total force exerted in any direction is equal to the mass of water being deviated, multiplied by the change of velocity in that direction. If the angle turned is B (see Figs. 28 and 29), the pressure or thrust in the direction before the turning is $P_x = (QwV/g)(1 - \cos B)$, where Q is the quantity flowing per second, w the weight of unit volume of liquid, V the velocity of the liquid, and g the gravity acceleration constant. If A is the cross section of the stream before turning, the equation may be written $P_x = 2Aw(1 - \cos B)V^2/2g$, thus introducing the velocity head in the flowing liquid. Taking Q in cu ft per sec and V in ft per sec the formula becomes, for water, $P_x = 1.94QV(1 - \cos B)$. For $B = 90$ deg and 180 deg respectively (Figs. 31 and 32), it becomes $P_x = 1.94QV$ and $3.88QV$. The pressure in a direction at right angles to the original direction is $P_y = (QwV/g) \sin B$, or $2Aw \sin BV^2/2g$, or, for water and ft-lb-sec units, $1.94QV \sin B$. With solids shaped as in Figs. 29 and 33, the components of the pressure in directions other than the original direction neutralize each other due to the divided stream. The **total resultant pressure** due to turning the water aside (P in Fig. 28) is $P = (QwV/g)\sqrt{2(1 - \cos B)}$ and its direction is 90 deg from midway between the original and final directions of the flowing liquid, *i.e.*, angle C in Fig. 28 = 90 deg − ½B. If a stream impinges squarely against a wall, as in Fig. 30, the effect is the same as it would be in Fig. 29 with $B = 90$ deg.

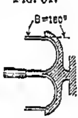

FIG. 33.

Gages for Measuring Pressures, Velocities, and Levels

The Pitot Tube. The Pitot tube shown on p. 252 is not readily adapted for insertion through a small hole in the wall of a pipe. Figures 34 and 35 illustrate representative tubes of more compact type. Such tubes have coefficients less than 1. For tubes as in Fig. 35, $V = 0.84\sqrt{2gh}$, *i.e.*, the indicated water column difference h is about $(1/0.84)^2$ or 42 percent greater than the h_v of Fig. 7. Very slight changes in the shape of a compact-type side-pressure-opening tube, as in Fig. 34, or in the location of the pressure openings, cause a change in the coefficient of the tube. For Fig. 34, V = 0.84 to $0.88\sqrt{2gh}$, depending on location of side openings and shape of tube; for precise work such tubes should be rated. A single-opening tube in connection with a "wall piezometer" (*i.e.*, either a single hole as Fig. 7, a pair of diametrically opposite holes, or a ring piezometer, see p. 259) is the simplest arrangement and least liable to errors resulting from imperfections in construction. The coefficient is unity, *i.e.*, $V = \sqrt{2gh}$, for a tube that has its impact

The solution is $b = -2a$, $c = -a$, $d = -a$, $e = -a$.
Whence $hl^{-2}v^{-1}t^{-1}q^{-1}$ is dimensionless.

For the variables for the other product there should be chosen a set not containing h, or l, v, t, q, and k, and it is required that $l^a v^b t^c q^d k^e$ be dimensionless. Work similar to that just carried through shows that $lvqk^{-1}$ is dimensionless, t dropping out, since $c = 0$. Hence the result is:

$$f_1\{(hl^{-2}v^{-1}t^{-1}q^{-1}),\ (lvqk^{-1})\} = \text{const},$$

which may be rewritten in the form:

$$h = l^2tvq.f(lvq/k).$$

This shows that the rate of heat transfer is proportional to the temperature difference, as was to be expected, and also that the heat transfer depends only on the product of velocity and heat capacity. *A single set of experiments* in which the way in which heat transfer varies with l is determined, would evidently now be sufficient to fix the form of f, and hence completely determine the solution.

"point" should not be a "needle point," but a conical point with a vertex angle of 90 to 120 deg, so as to produce a maximum of optical effect for slight variations from perfect contact of the point with the liquid surface. The use of a stilling box, such as the float pipe above described, is desirable especially for the hook gage (see Fig. 37).

In use, the hook-gage point is moved up from beneath until it just pierces the liquid surface. The point gage and plumb-bob gage are manipulated by lowering from above until a "bubble" shows contact with the liquid surface. If used for flowing water or a large surface of a tank or reservoir, where there are waves or surges, and where

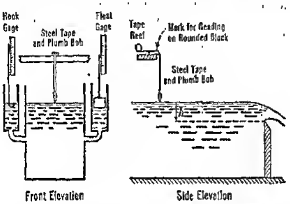

Fig. 37.—Hook, Plumb-bob and Float Gages.

a stilling box is not available, the gage should be set so that the average time durations during which the point is alternately submerged and exposed shall be as nearly equal as the observer can estimate. Even with a stilling box there may be surges of small amplitude, and several sets of observations may be necessary to assure a determination within 0.001 ft.

The float gage is the best of the gages mentioned for sensitiveness and accuracy. It automatically shows the small variations of water surface level, and the observer needs merely to watch the index on the float-stem. Any desired degree of damping out of minor or temporary fluctuations of water level may be accomplished by changing the size of the opening or by regulating a shut-off cock in the connecting pipe.

Whenever there is a perceptible vibration of the water surface, maximum and minimum readings should be taken, corresponding to the crests and troughs of the waves. The average will give the mean level in most cases.

Flow of a Viscous Fluid.

Let u, v, w = components of velocities along the x-, y-, z-axes

$$\rho = \text{fluid density} = \frac{\text{mass}}{\text{volume}}$$

μ = coefficient of viscosity

t = time

The differential equations of this problem are of the type

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial z} = \frac{\mu}{\rho}\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}\right)$$

Assume $V = k_V V_m$ where k_V is the scale factor for all velocities.
$l = k_l\, l_m$ where k_l is the scale factor for all lengths.
$\rho = k_\rho\, \rho_m$ where k_ρ is the scale factor for the fluid density. (6)
$\mu = k_\mu\, \mu_m$ where k_μ is the scale factor for the fluid viscosity.
$t = k_t\, t_m$ where k_t is the scale factor for all time.

The scale factor k_t is obviously not independent of the others. Since

$$V = \frac{l}{t} \quad\text{and}\quad V_m = \frac{l_m}{t_m}, \quad k_V V_m = \frac{k_l\, l_m}{k_t\, t_m}, \quad\text{or}\quad k_t = \frac{k_l}{k_V}$$

Upon substituting (6), equation (5) becomes

$$\frac{k_V}{k_t}\cdot\frac{\partial u_m}{\partial t_m} + \frac{k_V^2}{k_l}\cdot\left(u_m\frac{\partial u_m}{\partial x_m} + v_m\cdot\frac{\partial u_m}{\partial y_m} + w_m\cdot\frac{\partial u_m}{\partial z_m}\right) = \frac{k_\mu\cdot k_V}{k_\rho\cdot k_l^2}\cdot\left(\frac{\partial^2 u_m}{\partial x_m^2} + \frac{\partial^2 u_m}{\partial y_m^2} + \frac{\partial^2 u_m}{\partial z_m^2}\right)$$

The similarity conditions in this case are

$$\frac{k_V}{k_t} = \frac{k_V^2}{k_l} = \frac{k_\mu k_V}{k_\rho k_l^2}$$

The relation $\frac{k_V}{k_t} = \frac{k_V^2}{k_l}$ is automatically satisfied since $k_V = \frac{k_l}{k_t}$. The other condition is

$$\frac{k_V^2}{k_l} = \frac{k_\mu k_V}{k_\rho k_l^2} \quad\text{or}\quad \frac{k_\rho}{k_\mu}\cdot k_V k_l = 1$$

This condition states that

$$\frac{\frac{\rho}{\rho_m}\cdot\frac{V}{V_m}\cdot\frac{l}{l_m}}{\frac{\mu}{\mu_m}} = 1 \quad\text{or}\quad \frac{\rho V l}{\mu} = \frac{\rho_m V_m l_m}{\mu_m}$$

This quantity $R = \frac{\rho V l}{\mu}$ is the **Reynolds number.** In order to have similar conditions of flow on model and full scale, it is necessary that the Reynolds number be the same for each.

Whenever the equations of a problem are known, the above method of analysis is applicable. The method can also be applied if only the general nature of the factors involved in a problem are known.

Consider, for instance, the problem of determining the resistance of ships. In order for the paths of flow about the ship to be similar, it is necessary that the scale factor for the forces $k_F = F/F_m$ be the same for all the types of forces acting on a small fluid element. Assume that the wave

of the size of the units. But the condition that this be true involves the way in which the numerical magnitude of the various quantities which enter the equations vary with the size of the fundamental units, and this in turn is determined by the dimensions of these quantities.

In applying the method, the first step, therefore, is to write out the dimensions of all the quantities which enter. The dimensions of a quantity are determined by its definition in terms of the quantities which are selected as fundamental. (For example, the dimensions of velocity are LT^{-1}, because velocity is defined as distance travelled in unit time.) The choice of fundamental quantities is in large part a matter of convenience, and there is, therefore, nothing absolute about the dimensions of any quantity. In most engineering problems, the ordinary mechanical quantities, mass (M), time (T), and length (L), may most conveniently be taken as fundamental, with the addition of temperature (t), in problems involving temperature effects. *In the table on page 282 are given the dimensions of some of the most usual* quantities.

The theorems on which dimensional analysis is based are the following. (1) Any equation which continues to hold when the size of the fundamental units changes can be thrown into such a form that the variables enter the equations only through certain combinations which are dimensionless. To determine the possible number of such dimensionless combinations we have the π theorem (2) which states that the number of such combinations is in general equal to the difference between the number of variables and the number of fundamental units, but in exceptional cases may be greater than the difference. There is also another theorem (3) by which it can be proved that any dimensionless combination must be expressible as a product of powers of the variables.

An application of these theorems results in the statement of the following important result of dimensionless analysis: *Any general connection between the variables can be expressed in the form of an arbitrary function of all the independent dimensionless products of the variables set equal to a constant.*

The information contained in expressing the connection in this form is most useful, in spite of the arbitrary character of the function, because of the reduction in the number of the arguments from the large number of independent variables to the smaller number of dimensionless products. The whole theory of models is contained here, in which, by making a change in a comparatively small number of physical variables, the effect of changes in all the variables can be told.

Examples. (1) Beginning with the classical pendulum problem, what is known about the time of swing of a pendulum? This is evidently a problem in mechanics. The solution of the equation of motion will contain the parameters needed to describe the pendulum, namely its mass, length, and initial angular displacement, and the solution will also contain any quantities with dimensions which are necessary in writing down the equations

Quantity	Symbol	Dimensions
Length of pendulum	l	L
Mass of pendulum	m	M
Acceleration of gravity	g	LT^{-2}
Initial angular displacement	w	0
Time of swing	t	T

The general theorem now states that an arbitrary function of these two products is to be set equal to a constant, or $f_1\{(r^3Pv^{-1}D^{-1}), (r/l)\} = \text{const}$; or, $r^3Pv^{-1}D^{-1} = f_2(r/l)$; or, $D = (r^3P/v)f_3(r/l)$; where f_1, f_2 and f_3 are arbitrary functions.

Hence the delivery varies as the pressure difference, and inversely as the viscosity. Suppose now that it is known in addition, as very simple considerations show, that the flow is proportional to the pressure gradient, that is, to P/l. Then the formula shows that f_3 must be proportional to r/l, so that: $D = \text{const.} \times (r^4P/vl)$, and the additional and important result is obtained that the delivery is directly proportional to the fourth power of the radius.

If the condition that the section of the pipe be circular is given up and it is assumed to be elliptical, with major and minor axes, r_1 and r_2, then there is an additional dimensionless product, r_1/r_2, and the result may be put in the form:

$$D = (r_1^4P/vl)f(r_1/r_2),$$

where f is an unknown function, but as before, the result is obtained that the delivery through a pipe with a section of given geometrical shape is proportional to the fourth power of the linear dimensions of the section.

(3) Rayleigh's Problem of Heat Transfer. A solid body, of definite geometrical shape, but variable absolute dimensions, is fixed in a stream of liquid, and maintained at a definite temperature higher than the temperature of the liquid at points remote from the body. Required to find the rate at which heat is transferred from the body to the liquid.

In writing the fundamental equations which govern this problem, the fact that heat and mechanical energy are convertible will evidently not be made use of. This fact may therefore be ignored in framing the fundamental definitions which determine the dimensions, and the quantity of heat, H, may be used as one of the fundamental quantities. It is furthermore evident, since the mechanics of the situation is not involved, and the lines of flow in the liquid are determined only by the geometry, that the viscosity of the liquid will not enter those equations which determine heat transfer. The quantities and dimensions are:

Quantity	Symbol	Dimensions
Rate of heat transfer	h	HT^{-1}
Linear dimensions of body	l	L
Velocity	v	LT^{-1}
Temperature difference	t	t
Heat capacity of liquid per unit volume	q	$HL^{-3}t^{-1}$
Thermal conductivity of liquid	k	$HL^{-1}T^{-1}t^{-1}$

There are 6 variables and 4 fundamental quantities, and hence two dimensionless products. In general, these two products may be composed of any two sets of four chosen from the six variables. Since the problem concerns h, one of the products is chosen so as to contain h. It is required that $h^al^bv^ct^dq^e$, or $(HT^{-1})^aL^b(LT^{-1})^ct^d(HL^{-3}t^{-1})^e$ be dimensionless. This gives the equations:

$$\begin{array}{lllll} a & & & + e & = 0, \text{ condition on exponent of } H \\ -a & & - c & - & = 0, \text{ condition on exponent of } T \\ & b & + c & - 3e & = 0, \text{ condition on exponent of } L \\ & & d & - e & = 0, \text{ condition on exponent of } t \end{array}$$

THERMAL PROPERTIES OF BODIES AND THERMODYNAMICS

THERMAL PROPERTIES OF BODIES

The Measurement of Temperature

Thermometers. The scale of the constant-volume **hydrogen thermometer** is taken as the standard temperature scale. Within the limits of ordinary use, the scale of the mercury thermometer agrees closely with the standard scale, but above 500 F the divergence between the two scales may be appreciable.

The ordinary **mercury thermometer** may be used to about 600 F; this limit may be extended to 1000 F if the capillary tube above the mercury is filled with nitrogen or carbon dioxide under high pressure. The lower temperature limit for the mercury thermometer is −39 F. For lower temperatures, alcohol, pentane, or petroleum ether may be used as the thermometric substance. For stem exposure corrections, see Temperature Measurements, p. 1783. Very high temperatures are measured by various forms of **pyrometers** (see pp. 1785–1790).

Thermometer Scales. Let F and C denote the readings on the Fahrenheit and centigrade (or Celsius) scales, respectively, for the same temperature; then

$$C = \tfrac{5}{9}(F - 32), \qquad F = \tfrac{9}{5}C + 32$$

Table 1 gives corresponding readings on the two scales.

THEORY OF MODELS

BY

W. BOLLAY

REFERENCES: Prandtl and Tietjens, "Applied Hydro- and Aeromechanics," McGraw-Hill. Stodola-Loewenstein, "Steam and Gas Turbines," McGraw-Hill, Vol. 2, p. 1016.

Engineering problems that are too complicated for mathematical or graphical solution are generally studied by model tests. This procedure is used extensively in the design of ships, airplanes, hydraulic pumps, and turbines as well as in problems dealing with heat flow and complex elastic structures. In each case, a model is constructed which is geometrically similar to the full-size project. Measurements are made of the performance of the model including velocities, powers, temperatures, or stresses as the case may be. The problem of the theory of models is to determine the requisite conditions under which the performance of the model is similar to that of the full-size construction and to predict the behavior of the latter.

Consider for instance the **buckling of a column.** For a buckled column, the radius of curvature R is expressed in terms of the bending moment $M = Py$ and I, the moment of inertia of the cross section, as

$$\frac{1}{R} = \frac{M}{EI} = \frac{Py}{EI} \tag{1}$$

where P is the buckling load and y the sideward deflection of the column. The idea of the theory of models is that it makes no difference what the absolute scale is, by means of which the length l, the load P, or the elastic modulus E is measured. Thus assume that the relation between full-scale and model condition is expressed as

$$l = k_l l_m; \quad R = k_l R_m; \quad y = k_l y_m; \quad P = k_P P_m; \quad E = k_E E_m \tag{2}$$

where the subscript m refers to conditions on the model. The ratio k_l expresses the ratio between all corresponding length dimensions of model and full scale. If the model conditions are to be similar to full size, then equation (1) must also be satisfied in terms of the model scales, *i.e.*,

$$\frac{1}{R_m} = \frac{P_m y_m}{E_m I_m} \tag{3}$$

But if into (1) we substitute the relations (2), we get

$$\frac{1}{k_l R_m} = \frac{(k_P P_m)(k_l y_m)}{(k_E E_m)(k_l^4 I_m)}$$

or

$$\frac{1}{R_m} = \frac{k_P}{k_E k_l^2} \cdot \frac{P_m y_m}{E_m I_m} \tag{4}$$

In order for equation (4) to agree with (3), it is necessary that $\frac{k_P}{k_E k_l^2} = 1$, *i.e.*, $k_P = k_E k_l^2$. Thus if the buckling load is 100 lb on a quarter-scale model constructed out of a plastic with $\frac{1}{30}$ of the modulus of elasticity of the full-scale model, then the full-scale structure will carry $100 \times 30 \times (4)^2 = 48{,}000$ lb.

In dealing with problems in dynamics or heat flow, the fundamental equations describing the problem are generally differential equations. The procedure in these cases is analogous.

Table of Values for Interpolation in the Above Table

Degrees Fahrenheit......	1	2	3	4	5	6	7	8	9
Degrees centigrade*......	0.56	1.11	1.67	2.22	2.78	3.33	3.89	4.44	5.00

* All decimals in the table are repeating decimals; 37.78 is really 37.777 . . . . . .

motion is principally the result of the interaction between gravity forces and the inertia forces of the fluid. The gravity forces on a fluid element of length l are proportional to $\rho g l^3$, the inertia forces to mass $\times$ acceleration $=$ $(\rho l^3) \cdot \frac{l}{t^2} = (\rho l^3) \cdot \frac{V^2}{l} = \rho V^2 \cdot l^2$ since $V = \frac{l}{t}$. By the criterion for similar flow,

$$\rho g l^3 = k_F \cdot \rho_m g_m l_m^3$$
$$\rho V^2 l^2 = k_F \cdot \rho_m V_m^2 l_m^2$$

Therefore,

$$k_F = \frac{\rho}{\rho_m} \cdot \frac{g}{g_m} \cdot \frac{l^3}{l_m^3} = \frac{\rho}{\rho_m} \cdot \frac{V^2}{V_m^2} \cdot \frac{l^2}{l_m^2} \qquad \text{or} \qquad \frac{V^2}{gl} = \frac{V_m^2}{g_m l_m}$$

The quantity $F = \frac{V}{\sqrt{gl}}$ is called **Froude's number.** In making a test of a ship model in a towing tank, this quantity must be kept the same as full scale.

In the problem of **vibrations of an elastic body,** the important forces are the inertia forces and the elastic forces. The inertia force $\propto$ mass $\times$ acceleration $= (\rho l^3) \cdot \frac{l}{t^2} = \frac{\rho l^4}{t^2}$. The elastic force $\propto$ stress $\times$ area $= \sigma \cdot l^2 = \epsilon E \cdot l^2$ which is dimensionally the same as El^2 since the strain ϵ is dimensionless. The criterion for similarity is that

$$k_F = \frac{\frac{\rho l^4}{t^2}}{\frac{\rho_m l_m^4}{t^2}} = \frac{El^2}{E_m l_m^2} \qquad \text{or} \qquad \frac{\rho \frac{l^2}{t^2}}{E} = \frac{\rho_m \frac{l_m^2}{t_m^2}}{E_m} = C$$

where $C =$ **Cauchy's number.**

The problem of **heat conduction** is governed by the equation

$$\frac{\partial \theta}{\partial t} = a \left[\frac{\partial^2 \theta}{\partial x^2} + \frac{\partial^2 \theta}{\partial y^2} + \frac{\partial^2 \theta}{\partial z^2} \right]$$

where $\theta =$ temperature, $t =$ time, $a = \frac{k}{\gamma c}$, $k =$ coefficient of heat conduction, $\gamma c =$ specific heat per unit volume, $\gamma =$ weight per unit volume, $x, y, z =$ rectangular coordinates. The similarity conditions lead to

$$\frac{k_\theta}{k_t} = k_a \cdot \frac{k_\theta}{k_l^2}$$

where $k_\theta = \frac{\theta}{\theta_m}$ etc. $\qquad$ or $\qquad \frac{k_a \cdot k_t}{k_l^2} = 1 \qquad$ i.e. $\qquad \frac{at}{l^2} = \frac{a_m t_m}{l_m^2} = F_0$

where F_0 is the **Fourier number.**

The **linear shrinkage of castings** is approximately as follows:

Bar iron, rolled	1:55	Cast iron	1:96	Steel, puddled	1:72
Bell metal	1:65	Gun metal	1:134	Steel, wrought	1:64
Bismuth	1:265	Iron, fine grained	1:72	Tin	1:128
Brass	1:65	Lead	1:92	Zinc, cast	1:62
Bronze	1:63	Steel castings	1:50	8 Cu + 1Sn (by wt)	1:134

The coefficients of cubical expansion for different gases at ordinary temperatures are about the same. From 0 to 212 F and at atmospheric pressure, the values multiplied by 1,000 are as follows: for NH_3, 2.11; CO, 2.04; CO_2, 2.07; H_2, 2.03; NO, 2.07.

Measurement of Heat

Units of Heat. Many units of heat have been dependent on the experimentally determined properties of some substance. To eliminate experimental variations, the unit of heat may be defined in terms of fundamental units. The International Steam Table Conference (London, 1929) defines

TABLE OF VALUES FOR INTERPOLATION IN THE ABOVE TABLE

Degrees centigrade	1	2	3	4	5	6	7	8	9
Degrees fahrenheit	1.8	3.6	5.4	7.2	9.0	10.8	12.0	14.4	16.2

compound at room temperature is equal to the sum of the specific heats of the atoms forming the compound. The values given in the following table are to be used in connection with Kopp's law.

Constants for Kopp's Law

Elements	Specific Heats of the Atoms	Elements	Specific Heats of the Atoms
Heavy elements	6.4	Oxygen	4.0
Boron	2.7	Phosphorus	5.4
Carbon	1.8	Silicon	3.5
Fluorine	5.0	Sulphur	5.4
Hydrogen	2.3		

Example. Specific heat of the atoms of $Na_2SO_4 = 2(6.4) + 5.4 + 4(4) = 34.2$ Molecular weight $Na_2SO_4 = 142$. Specific heat $= 34.2/142 = 0.24$ (I.C.T. value = 0.20). Errors of 20 percent are not uncommon using Kopp's law.

Table 9. Mean Specific Heats of Various Solids and Liquids between 32 and 212 F

(For gases, see p. 310 and Fig. 1; for pure metals, p. 608; for refractories, p. 731)

Specific Heats of Gases. For monatomic gases, the specific heats do not vary with temperature, and k, the value of c_p/c_v, is 1.66. For diatomic

If the pressure readings of a constant-volume hydrogen thermometer are extrapolated to zero pressure, it is found that the corresponding temperature is −273.16 C, or −459.69 F. It is convenient to have a so-called **absolute temperature scale** on which zero corresponds with zero pressure on the hydrogen thermometer. Such a scale has fundamental thermodynamic significance and agrees very closely with the thermodynamic temperature scale. The absolute scales in use are:

Degrees Kelvin (K) = degrees centigrade + 273.16.

Degrees Rankine (R) = degrees Fahrenheit + 459.69.

Fixed Temperatures. When calibrating thermometers, it is convenient to have fixed temperatures. The following are recommended by the *U. S. Bureau of Standards:*

Substance	Deg F	Deg C	Substance	Deg F	Deg C
Liquid naphthalene boils at	424.2	217.9	Liquid copper-silver eutectic solidifies at	1434	779.0
Liquid tin solidifies at	449	232	Solid silver melts at	1761	960.5
Liquid benzophenone boils at	582.6	305.9	Solid gold melts at	1945.5	1063

On a molal basis, the average values of specific heat for some of the more common gases are given by Fig. 1. These values have been corrected to zero pressure but they are practically the same at 1 atm. Table 10 gives equations for specific heats for several gases at a constant pressure of 1 atm.

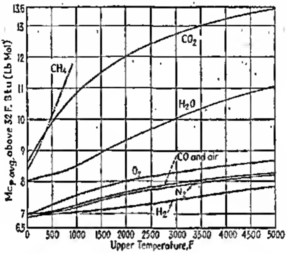

FIG. 1.—Values of the Mean Molal Specific Heat at Constant Pressure, above 32 F.

Specific Heat of Mixtures. If w_1 lb of a substance at temperature t_1 and with specific heat c_1 is mixed with w_2 lb of a second substance at temperature

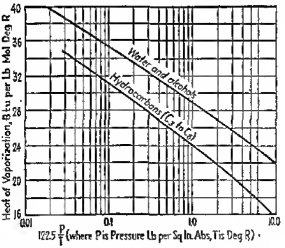

FIG. 2.—Hildebrand Function for Enthalpy of Vaporization

t_2 and with specific heat c_2, provided chemical reaction, heat evolution, or heat absorption do not occur, the specific heat of the mixture is

$$c_m = (w_1c_1 + w_2c_2)/(w_1 + w_2)$$

and the temperature of the mixture is

$$t_m = (w_1c_1t_1 + w_2c_2t_2)/(w_1c_1 + w_2c_2)$$

In general, $t_m = \Sigma wct/\Sigma wc$.

temperature of 1 deg. Likewise, the **coefficient of cubical expansion** of a solid, liquid, or gas is the increment of volume of a unit volume for a rise of temperature of 1 deg. Denoting these coefficients by a' and a''', respectively,

$$a' = \frac{1}{l}\frac{dl}{dt} \qquad a''' = \frac{1}{V}\frac{dV}{dt}$$

in which l denotes length, V volume, and t temperature. For homogeneous solids $a''' = 3a'$ and the **coefficient of superficial expansion** $a'' = 2a'$.

The coefficients of expansion are, in general, dependent upon the temperature, but for ordinary ranges of temperature, constant mean values may be taken. If lengths, areas, and volumes at 32 F (0 C) be taken as standard, then these magnitudes at other temperatures t_1 and t_2 are related as follows:

$$\frac{l_1}{l_2} = \frac{1 + a't_1}{1 + a't_2} \qquad \frac{A_1}{A_2} = \frac{1 + a''t_1}{1 + a''t_2} \qquad \frac{V_1}{V_2} = \frac{1 + a'''t_1}{1 + a'''t_2}$$

Since for solids and liquids the expansion is small, the preceding formulas for these bodies become approximately

$$l_2 - l_1 = a'l_1(t_2 - t_1). \quad A_2 - A_1 = a''A_1(t_2 - t_1). \quad V_2 - V_1 = a'''V_1(t_2 - t_1).$$

For certain metals, the variation of the coefficient of expansion with temperature is given by an equation in which, denoting by l_0 the length at 32 F, and by l the length at temperature t, the following relation is obtained:

$$l = l_0\left[1 + a\left(\frac{t - 32}{1000}\right) + b\left(\frac{t - 32}{1000}\right)^2\right]$$

The following table gives values of the constants.

Metal	1000 a	1000 b	Temperature range, deg F
Aluminum	12.58	3.0	32–1130
Cast iron	5.441	1.747	32–1160
Ingot iron	6.375	1.636	32–1380
Malleable iron	6.503	1.622	32–930
Ingot steel	6.212	1.623	32–1380
Copper	9.278	1.244	32–1160
Nickel	7.652	1.023	32–1830

Gruneisen finds that a' varies directly as the specific heat.

General Principles of Thermodynamics

Thermodynamics is the study of changes in which energy is involved. The quantity of matter under consideration is called the **system**, and everything else is spoken of as the **surroundings**. Any change the system may undergo is known as a **process**. Any process or series of processes that returns the system to its original condition or state is called a **cycle**.

Heat is energy **in transit** from one mass to another because of a temperature difference between the two. Whenever a force of any kind acts through a distance, **work** is done. Like heat, work is also energy in transit. Work is to be differentiated from the capacity of a quantity of energy to do work.

Notation.

$A = 1/J$ = reciprocal of mechanical equivalent.
B = availability (by definition, $B = H - T_oS$).
c_p = specific heat at constant pressure.
c_v = specific heat at constant volume.
E = total energy associated with a system.
H, h = enthalpy, Btu (by definition $h = u + Apv$).
J = mechanical equivalent of heat = 778.26 ft-lb per Btu = 4.1861 joules per cal.
$k = c_p/c_v$.
M = molecular weight.
p = absolute pressure, lb per sq ft.
Q, q = quantity of heat absorbed by the system from the surroundings, Btu.
R = perfect gas constant.
S, s = entropy.
t = temperature, deg F.
$T = t + 459$ [illegible] erature = deg R.
T_o = sink or [illegible]
U, u = internal energy, Btu.
V = linear velocity, fps (or total volume).

the Steam Table (IT) calorie as $\frac{1}{860}$ of a watthour. One British thermal unit (Btu) is defined as 251.996 IT cal, or 778.26 ft-lb.

Previously, the Btu was defined as the heat necessary to raise one pound of water one degree Fahrenheit at some arbitrarily chosen temperature level. Similarly, the calorie was defined as the heat required to heat one gram of water one degree centigrade at 15 C (or at 17.5 C). These units are roughly the same in value as those mentioned above.

Heat Capacity and Specific Heat. The amount of heat required to raise unit mass of a material 1 deg in temperature is called the **heat capacity** of that material. The ratio of the amount of heat required to raise unit mass of a material 1 deg to that required to raise unit mass of water 1 deg at some specified temperature is the **specific heat** of the material. For most engineering purposes, heat capacities may be assumed numerically equal to specific heats. Two heat capacities are generally used, that at constant pressure c_p and that at constant volume c_v. For unit mass, the instantaneous heat capacities are defined as

$$\left(\frac{\partial Q}{\partial t}\right)_p = c_p \qquad \left(\frac{\partial Q}{\partial t}\right)_v = c_v$$

Over a range in temperature, the mean heat capacities are given by

$$c_{p_m} = \frac{1}{t_2 - t_1}\int_{t_1}^{t_2} c_p dt, \qquad c_{v_m} = \frac{1}{t_2 - t_1}\int_{t_1}^{t_2} c_v dt$$

Denoting by c the heat capacity, the heat required to raise the temperature of w lb of a substance from t_1 to t_2 is $Q = wc(t_2 - t_1)$, provided c is a constant.

In general, c varies with the temperature, though for moderate temperature ranges a constant mean value may be taken. If, however, c is taken as variable, then $Q = w\int_{t_1}^{t_2} c dt$. The *mean* heat capacity from 0 to t deg is given by $c_m = \frac{1}{t}\int_0^t c dt$. If $c = a_1 + a_2 t + a_3 t^2 + \cdots$

$$c_m = a_1 + \tfrac{1}{2}a_2 t + \tfrac{1}{3}a_3 t^2 + \cdots$$

Specific Heat of Water at Constant Pressure
(Interpolated from Keenan and Keyes Tables)

Temp, deg F	Pressure, lb per sq in.			
...	1,000	2,000	4,000	6,000
200	1.0	1.0	0.99	0.98
400	1.07	1.06	1.05	1.04
600	....	1.45	1.29	1.21
680	....	....	1.77	1.45

Specific Heat of Water at 1 Atm (I.C.T.)

Temp, deg F	32	50	100	150	212
c_p	1.001	1.002	1.004	1.009	1.021

Specific Heat of Solids. For elements near room temperature, the specific heat may be approximated by the rule of Dulong and Petit, that the specific heat at constant volume for one atomic weight of any solid element is 6.4. For solid compounds at about room temperature, Kopp's approximation is often useful. This states that the specific heat of a solid

starts and finishes with the system in the same state is called a **reversible cycle.**

Flow Processes. With **steady flow,** the conditions at any point in an apparatus through which a fluid is flowing do not change progressively with time. Steady-flow processes involving only mechanical effects are equivalent to similar non-flow processes occurring between two weightless frictionless diaphragms or pistons moving at constant pressure with the system as a whole in motion. Under these circumstances, the total work done by or on a unit amount of fluid is made up of that done on the two diaphragms $p_2v_2 - p_1v_1$ and that done on the rest of the surroundings $\int pdv - p_2v_2 + p_1v_1$. Differentiating, $pdv - d(pv) = -vdp$. The net, useful flow work done on the surroundings is $-\int vdp$. This is often called the shaft work. The net, useful or shaft work differs from the total work by $p_2v_2 - p_1v_1$. The first-law equation may be written to indicate this result

$$Jq - W_{\text{net}} = Ju_{12} + p_2v_2 - p_1v_1 + \frac{1}{2g}(V_2^2 - V_1^2) + X_2 - X_1$$

or since by definition

$$Ju + pv = Jh$$

$$Jq - W_{\text{net}} = Jh_{12} + \left(\frac{V^2}{2g}\right)_{12} + X_{12}$$

If all net work effects are mechanical,

$$Jq + \int vdp = Jh_{12} + \left(\frac{V^2}{2g}\right)_{12} + X_{12}$$

Since in evaluating $\int vdp$ the pressure is that *effectively* applied to the surroundings, the integration cannot usually be performed except for reversible processes.

If a fluid is passed adiabatically through a conduit (*i.e.*, without heat exchange with the conduit), without doing any net or useful work, and if velocity and potential effects are negligible, $h_{12} = 0$. A process of the kind indicated is the Joule-Thomson flow (see p. 361), and the ratio $(\partial T/\partial p)$ for such a flow is the Joule-Thomson coefficient.

If a fluid is passed through a non-adiabatic conduit without doing any net or useful work and if velocity and potential effects are negligible, $Q = wh_{12}$. This equation is important in the calculation of heat balances on flow apparatus, *e.g.*, condensers, heat exchangers, and coolers.

The second law of thermodynamics (p. 305) is a statement that conversion of heat to work is limited by the temperature at which conversion occurs. It may be shown that

1. No cycle can be more efficient than a reversible cycle operating between given temperature limits.

2. The efficiency of all reversible cycles absorbing heat only at a single constant higher temperature T_1 and rejecting heat only at a single constant lower temperature T_2 must be the same.

3. For all such cycles, the efficiency is

$$e = \frac{W}{Q_1} = \frac{T_1 - T_2}{T_1}$$

This is usually called the **Carnot cycle efficiency.** By the first law $W = Q_1 + Q_2$,

$$(Q_1 + Q_2)/Q_1 = (T_1 - T_2)/T_1$$

gases (oxygen, nitrogen, etc.), the specific heats vary with temperature but for many purposes may be assumed constant over considerable ranges of temperature. For diatomic gases, k is approximately 1.40. For more complex gases, generalizations are not possible. Specific heat increases with molecular complexity, and the value of k decreases (see also Table 15).

Properties of gases are, usually, most readily correlated on the mol basis. A pound mol is the weight in pounds equal to the molecular weight. Thus 1 pound mol of oxygen weighs 32 lb. At the same pressure and temperature, the volume of one mol is the same for all perfect gases, *i.e.*, following the gas laws. For perfect gases, $Mc_p - Mc_v = AMR = 1.987$.

$$c_v = AR/(k-1); \qquad c_p = ARk/(k-1)$$

Table 10. Specific Heats of Gases at 1 Atm

Gas	Symbol	Equation for C_p in Btu per mol	Temp range, deg R	Source
Oxygen	O_2	$11.515 - \left(\frac{172}{\sqrt{T}}\right) + \left(\frac{1530}{T}\right)$	540–5000	a
		$11.515 - \left(\frac{172}{\sqrt{T}}\right) + \left(\frac{1530}{T}\right) + \left(\frac{0.05(T-4000)}{1000}\right)$	5000–9000	a
Nitrogen	N_2	$9.47 - \left(\frac{3.47 \times 10^3}{T}\right) + \left(\frac{1.16 \times 10^6}{T^2}\right)$	540–5000	a
Carbon monoxide	CO	$9.46 - \left(\frac{3.29 \times 10^3}{T}\right) + \left(\frac{1.07 \times 10^6}{T^2}\right)$	540–5000	a
Hydrogen	H_2	$5.76 + \left(\frac{0.578T}{1000}\right) + \left(\frac{20}{\sqrt{T}}\right)$	540–4000	a
		$5.76 + \left(\frac{0.578T}{1000}\right) + \left(\frac{20}{\sqrt{T}}\right) - \left(\frac{0.33(T-4000)}{1000}\right)$	4000–9000	a
Water	H_2O	$19.86 - \left(\frac{597}{\sqrt{T}}\right) + \left(\frac{7500}{T}\right)$	540–5000	a
Carbon dioxide	CO_2	$16.2 - \left(\frac{6.53 \times 10^3}{T}\right) + \left(\frac{1.41 \times 10^6}{T^2}\right)$	540–6300	a
Methane	CH_4	$4.22 + 8.211 \times 10^{-3}T$	492–1800	b
		$27.0 - \frac{14{,}400}{T}$	1800–5940	b
Ethylene	C_2H_4	$6.0 + 8.33 \times 10^{-3}T$	720–1440	c
Ethane	C_2H_6	$6.6 + 13.33 \times 10^{-3}T$	720–1440	c
Ethyl alcohol	C_2H_6O	$4.5 + 21.1 \times 10^{-3}T$	680–1120	c
Methyl alcohol	CH_4O	$2.0 + 16.67 \times 10^{-3}T$	680–1100	c
Benzene	C_6H_6	$6.5 + 28.9 \times 10^{-3}T$	520–1120	c
Octane	C_8H_{18}	$14.4 + 53.3 \times 10^{-3}T$	720–1440	c
Dodecane	$C_{12}H_{26}$	$19.6 + 80.0 \times 10^{-3}T$	720–1440	c

[c] Parks and Huffman, *Am. Chem. Soc. Mon.* 60, 1932.

This function is of particular importance in processes where chemical changes occur. For reversible isothermal steady-flow processes, or for reversible constant-pressure isothermal non-flow processes, change in free energy is equal to net work.

Helmholtz free energy, $\psi = U - TS$, is equal to the work during a constant-volume isothermal reversible non-flow process.

All three of these functions B, Z, and ψ are point functions, and like E, H, and S their differentials are complete or perfect.

Perfect Differentials. Maxwell Relations. If z is some function of x and y, in general

$$dz = \left(\frac{\partial z}{\partial x}\right)_y dx + \left(\frac{\partial z}{\partial y}\right)_x dy$$

Substituting M for $\left(\frac{\partial z}{\partial x}\right)_y$ and N for $\left(\frac{\partial z}{\partial y}\right)_x$

$$dz = M\,dx + N\,dy$$

But $\frac{\partial}{\partial y}\left(\frac{\partial z}{\partial x}\right) = \frac{\partial}{\partial x}\left(\frac{\partial z}{\partial y}\right)$ or $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$. This is Euler's criterion for integrability. A perfect differential has the characteristics of dz stated above. Many important thermodynamic relations may be derived from the appropriate point function by the use of this relation. Some of these relations follow:

Table 14. Maxwell Relations

Function	Differential	Maxwell relation
$\Delta u = q - W$	$du = T\,ds - Ap\,dv$	$\left(\frac{\partial T}{\partial v}\right)_s = -A\left(\frac{\partial p}{\partial s}\right)_v$
$h = u + Apv$	$dh = T\,ds + Av\,dp$	$\left(\frac{\partial T}{\partial p}\right)_s = A\left(\frac{\partial v}{\partial s}\right)_p$
$\psi = u - Ts$	$d\psi = -s\,dT - Ap\,dv$	$\left(\frac{\partial s}{\partial v}\right)_T = A\left(\frac{\partial p}{\partial T}\right)_v$
$z = h - Ts$	$dz = -s\,dT + Av\,dp$	$\left(\frac{\partial s}{\partial p}\right)_T = -A\left(\frac{\partial v}{\partial T}\right)_p$

By holding certain variables constant, a second set of relations is obtained.

Differential	Independent variable held constant	Relation
$du = T\,ds - Ap\,dv$	s	$\left(\frac{\partial u}{\partial v}\right)_s = -Ap$
	v	$\left(\frac{\partial u}{\partial s}\right)_v = T$
$dh = T\,ds + Av\,dp$	s	$\left(\frac{\partial h}{\partial p}\right)_s = Av$
	p	$\left(\frac{\partial h}{\partial s}\right)_p = T$
$d\psi = -s\,dT - Ap\,dv$	T	$\left(\frac{\partial \psi}{\partial v}\right)_T = -Ap$
	v	$\left(\frac{\partial \psi}{\partial T}\right)_v = -s$
$dz = -s\,dT + Av\,dp$	T	$\left(\frac{\partial z}{\partial p}\right)_T = Av$
	p	$\left(\frac{\partial z}{\partial T}\right)_p = -s$

To raise the temperature of w_1 lb of a substance having a specific heat c_1 from t_1 to t_m, the weight w_2 of a second substance required is

$$w_2 = w_1c_1(t_m - t_1)/c_2(t_2 - t_m)$$

For mixing two bodies of the same (perfect) gas at constant pressure,

$$t_m = [(V_1 + V_2)/(V_1/T_1 + V_2/T_2)] - 459.69$$

Specific Heat of Solutions. For aqueous solutions of salts, the specific heat may be estimated by assuming the specific heat of the solution equal to that of the water alone. Thus, for a 20 percent by weight solution of sodium chloride in water, the specific heat would be approximately 0.8.

Latent Heats. For pure substances, the heat effects accompanying changes in state at constant pressure are known as latent effects, because no temperature change is evident. Heat of fusion, vaporization, sublimation, and change in crystal form are examples. Heats of vaporization at low pressures for pure liquids of similar chemical characteristics are well correlated by the methods proposed by Hildebrand. Such a correlation is given in Fig. 2.

Example. For water at 25 lb per sq in. abs and 240 F, the heat of vaporization is 952 Btu. Referring to Fig. 2, $122.5\dfrac{25}{240 + 460} = 4.4$, and the corresponding value of the molal heat of vaporization is $24.6(240 + 460) = 17{,}200$ Btu per lb mol or 958 Btu per lb.

Vapor Pressures. At a specified temperature, a pure liquid can exist in equilibrium contact with its vapor at but one pressure, its vapor pressure. A plot of these pressures against the corresponding temperatures is known as a vapor-pressure curve.

Presentation of Thermal Properties. For calculation of numerical results, experimentally determined properties of substances must be available. These properties may be presented in several different ways.

1. As equations of state, *e.g.*, the perfect gas laws and the van der Waals equation.
2. As charts or graphs.
3. As tables.
4. As approximations which may be useful when more reliable data are not available.

The Perfect Gas Laws. At low pressures and high enough temperatures, in the absence of chemical reaction, all gases approach a condition such that their *P-V-T* properties may be expressed by the simple relation

$$pv = RT$$

in which R is a constant. If v is expressed as volume per unit weight, the value of the constant R will be different for different gases. If v is expressed as the volume of one molecular weight of gas, then R is the same for all gases in any chosen system of units.

In general, for any amount of gas, the perfect gas equation becomes

$$pV = NMRT$$

Table 15. Properties of Gases

For more accurate values of specific heats, see pp. 301, 302.

[a] For accurate values of atomic weights, see p. 530.

[b] For values at 60 F, multiply by 1.0154.

[c] Very rough values applying to low pressures and temperatures only. See steam tables, pp. 328 to 335, for more exact values.

v = volume, cu ft.
w = weight of substance under consideration, lb.
W = external work performed on surroundings during a change of state.
X = distance above or below a chosen datum.
$Y = \left(\frac{p_1}{p_2}\right)^{(k-1)/k} - 1$
Z = free energy (by definition, $Z = H - TS$).
ψ = Helmholtz free energy (by definition, $\psi = U - TS$).

In this notation, small letters denote magnitudes referred to unit weight of the substance, capital letters corresponding magnitudes referred to w units of weight. Thus, v denotes the volume of 1 lb, $V = wv$, the volume of w lb. Similarly, $U = wu$, $S = ws$, etc. Subscripts are used to indicate different states; thus, p_1, v_1, T_1, u_1, s_1 refer to state 1, p_2, v_2, T_2, u_2, s_2 refer to state 2. Q_{12} is used to denote the heat absorbed by a body during the change from state 1 to state 2, and W_{12} denotes the external work done during the same change.

The two fundamental and general laws of thermodynamics are: (1) Energy may be neither created nor destroyed. (2) It is impossible to bring about any change or series of changes the sole net result of which is transfer of energy as heat from a low temperature to a high temperature, or, in other words, heat will not of itself flow from low to high temperatures.

The first law of thermodynamics, the statement that energy can be neither created nor destroyed, may be stated mathematically

$$JQ - W = JE_{12}$$

In this equation, W and Q are the heat and work effects as the system passes from the initial to the final state. Care must be exercised in giving the correct signs to Q and W. Heat added to the system or withdrawn from the surroundings is positive, and work done by the system is positive. All terms in the first-law equation must be expressed in the same energy units. The total energy associated with a system E is often called its **internal or intrinsic energy.** Sometimes parts of this may be separated; *e.g.*, the energy due to motion or the kinetic energy $wV^2/2g$, which is important only when flow velocities are considerable, or that due to position above or below a chosen datum, the potential energy which is nearly always negligible. The residual energy of the system is U. The first law might therefore be written

$$JQ - W = JU_{12} + \frac{w}{2g}(V_2^2 - V_1^2) + w(X_2 - X_1)$$

Since as stated above, the last two terms are often negligible they will be omitted for simplicity except when such omission would introduce appreciable error.

Work done in overcoming a fluid pressure is measured by $W = \int p\,dv$, where p is the pressure *effectively* applied to the surroundings for doing work and dv represents the change in volume of the system.

Reversible and Irreversible Processes. A reversible process is one in which both the system and surroundings may be returned to their original states. After an irreversible process, this is not possible. No process involving friction or an unbalanced potential can be reversible. No loss in ability to do work is suffered because of a reversible process but there is always a loss in ability to do work because of an irreversible process. All actual processes are irreversible. Any series of reversible processes that

No entirely satisfactory method for calculation for gaseous mixtures has been developed, but the use of average critical constants as proposed by Kay, (*Ind. Eng. Chem.*, **28**, 1936, p. 1014) is easy and gives satisfactory results under conditions considerably removed from the critical. He assumes the

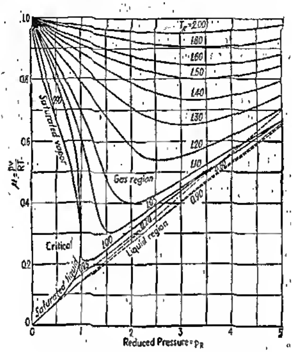

FIG. 3.—The μ Chart (Low Range).

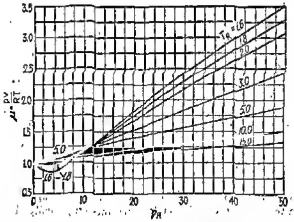

FIG. 4.—The μ Chart (High Range).

gaseous mixture can be treated as if it were a single pure gas with a pseudo-critical pressure and temperature estimated by a method of molal averaging.

$$(T_c)_{\text{mixture}} = (T_c)_a y_a + (T_c)_b y_b + (T_c)_c y_c + \cdots$$
$$(p_c)_{\text{mixture}} = (p_c)_a y_a + (p_c)_b y_b + (p_c)_c y_c + \cdots$$

where $(T_c)_a$ is the critical temperature of pure a, etc.; $(p_c)_a$ is the critical pressure of pure a, etc.; and y_a is the mol fraction of a, etc. For a gaseous

By algebraic rearrangement,

$$(Q_1/T_1) + (Q_2/T_2) = 0$$

Clapeyron Equation.

$$\frac{dp}{dT} = \frac{Q}{ATV_{12}}$$

This important relation is useful in calculations relating to constant-pressure evaporation of pure substances. In that case the equation may be written

$$v_{fg} = \frac{h_{fg}}{AT}\frac{1}{(dp/dT)}$$

where the symbols are as on p. 321.

Entropy. For reversible cyclical processes in which the temperature varies during heat absorption and rejection, *i.e.*, for any *reversible cycle*, $\int \frac{dQ}{T} = 0$. Consequently, for any *reversible process* $\int \frac{dQ}{T}$ is not a function of the particular *reversible path* followed. This integral is called the entropy change, or $\int_1^2 \frac{dQ_{rev}}{T} = S_2 - S_1 = S_{12}$. The entropy of a substance is dependent only on its state or condition. Mathematically, dS is a complete or perfect differential and S is a point function in contrast with Q and W which are path functions. For any reversible process, the change in entropy of the system and surroundings is zero, whereas for any irreversible process, the net entropy change is positive.

All actual processes are irreversible and therefore occur with a decrease in the amount of energy available for doing work, *i.e.*, with an increase in unavailable energy. The increase in unavailable energy is the product of two factors, T_0 the lowest available temperature for heat discard (practically always the temperature of the atmosphere) and the net change in entropy. The increase in unavailable energy is $T_0\,\Delta S_{net}$. Any process that occurs of itself (any spontaneous process) will proceed in such a direction as to result in a net increase in entropy. This is an important concept in the application of thermodynamics to chemical processes.

Availability of a system or quantity of energy is defined as $B = H - T_0S$. In this equation, all quantities except T_0 refer to the system irrespective of the state of the surroundings. T_0 is the lowest temperature available for heat discard. The preceding definition assumes the absence of velocity, potential, and similar effects. When these are not negligible, proper allowance must be made, *e.g.*, $B = H - T_0S + \frac{wV^2}{2Jg} + \frac{wX}{J}$. By substitution of $Q = T_0S_{12}$ in the appropriate first-law expressions, it may be shown that for any steady-flow process, or for any constant-pressure non-flow process, decrease in availability is equal to the maximum possible (reversible) net work effect with a sink for heat discard at T_0.

The availability function B is of particular value in the thermodynamic analysis of changes occurring in the stages of a turbine and is of general utility in determining thermodynamic efficiencies, *i.e.*, the ratio of actual work performed during a process to that which theoretically should have been performed.

Free energy, the Gibbs function, is defined as

$$Z = H - TS$$

3. Isothermal. (Constant Temperature): $p_2/p_1 = V_1/V_2$.

$U_2 - U_1 = 0$. $W_{12} = wRT \log_e(V_2/V_1) = p_1V_1 \log_e(V_2/V_1)$.

$Q_{12} = AW_{12}$. $s_2 - s_1 = Q_{12}/T = wAR \log_e(V_2/V_1)$.

40.0	13.94	17.07	21.63	28.68	2.869	2.343	1.850	1.398

By equating these various terms in the third column which are equal, one may obtain

$$\left(\frac{\partial u}{\partial s}\right)_v = \left(\frac{\partial h}{\partial s}\right)_p \qquad \left(\frac{\partial u}{\partial v}\right)_s = \left(\frac{\partial \psi}{\partial v}\right)_T$$

$$\left(\frac{\partial h}{\partial p}\right)_s = \left(\frac{\partial z}{\partial p}\right)_T \qquad \left(\frac{\partial z}{\partial T}\right)_p = \left(\frac{\partial \psi}{\partial T}\right)_v$$

By mathematical manipulation of equations previously given, the following important relations may be formulated:

$$c_v = \left(\frac{\partial q}{\partial T}\right)_v = T\left(\frac{\partial s}{\partial T}\right)_v = \left(\frac{\partial u}{\partial T}\right)_v$$

$$c_p = \left(\frac{\partial q}{\partial T}\right)_p = T\left(\frac{\partial s}{\partial T}\right)_p = \left(\frac{\partial h}{\partial T}\right)_p$$

$$c_p - c_v = AT\left(\frac{\partial v}{\partial T}\right)_p\left(\frac{\partial p}{\partial T}\right)_v$$

$$\left(\frac{\partial c_v}{\partial v}\right)_T = AT\left(\frac{\partial^2 p}{\partial T^2}\right)_v \qquad \left(\frac{\partial c_p}{\partial p}\right)_T = -AT\left(\frac{\partial^2 v}{\partial T^2}\right)_p$$

Relations involving q, u, h, and s:

$$dq = c_v dT + AT\left(\frac{\partial p}{\partial T}\right)_v dv = c_p dT - AT\left(\frac{\partial v}{\partial T}\right)_p dp$$

$$du = c_v dt + A\left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right]dv$$

$$dh = c_p dT - A\left[T\left(\frac{\partial v}{\partial T}\right)_p - v\right]dp$$

$$ds = c_v\frac{dT}{T} + A\left(\frac{\partial p}{\partial T}\right)_v dv = c_p\frac{dT}{T} - A\left(\frac{\partial v}{\partial T}\right)_p dp$$

Since $q - AW = u_{12}$ and $h = u + Apv$, for reversible processes

$$du = T\,ds - Apdv \qquad \text{and} \qquad dh = du + Apdv + Avdp$$

it follows that

$$Av = -T\left(\frac{\partial s}{\partial p}\right)_T + \left(\frac{\partial h}{\partial p}\right)_T$$

But from Table 14, $A\left(\frac{\partial v}{\partial T}\right)_p = -\left(\frac{\partial s}{\partial p}\right)_T$

Therefore, $\left(\frac{\partial h}{\partial p}\right)_T = A\left[v - T\left(\frac{\partial v}{\partial T}\right)_p\right]$

Similarly,

$$\left(\frac{\partial u}{\partial v}\right)_T = -A\left[p - T\left(\frac{\partial p}{\partial T}\right)_v\right]$$

These last two equations give in terms of p, v, and T the necessary relations that must hold for any system, however complex. An equation in p, v, and T for the properties of a substance is called an equation of state. These two equations applicable to any substance or system are known as **thermodynamic equations of state.**

from Moss and Smith, "Engineering Computations for Air and Gases," *Trans. A.S.M.E.*, 1929) which is calculated for $(k - 1)/k = 0.29$, or $k = 1.3947$. These values apply to normal air with 36 percent humidity and to perfect diatomic gases. For values of (p_2/p_1) greater than 10, the entries in Table 16 for $n = 1.4$ are available; these give the quantity $Y + 1$.

Determination of Exponent n. Lay off successive values of p and V, measured at chosen points on the curve under investigation, on logarithmic cross-section paper; or, lay off values of $\log p$ and $\log V$ on ordinary cross-section paper. If n is a constant, the points will lie in a straight line, and the slope of the line gives the value of n.

If two representative points (p_1, V_1 and p_2, V_2) be chosen, then

$$n = (\log p_1 - \log p_2)/(\log V_2 - \log V_1)$$

Several pairs of points should be used to test the constancy of n.

Changes of State with Variable Specific Heat. In case of a considerable range of temperature, the assumption of constant specific heat is not permissible, and the equations referring to changes of state must be suitably modified. Experiments on the specific heat of various gases show that the specific heat may sometimes be taken as a linear function of the temperature; thus, $c_v = a + bT$; $c_p = a' + bT$. In that case, the following expressions apply for the change of internal energy and entropy, respectively:

$$U_2 - U_1 = w[a(T_2 - T_1) + 0.5b(T_2^2 - T_1^2)]$$

$$S_2 - S_1 = w[a \log_e (T_2/T_1) + b(T_2 - T_1) + AR \log_e (V_2/V_1)]$$

and for an isentropic change,

$$W_{12} = J(U_1 - U_2)$$

$$AR \log_e (p_2/p_1) = (a + AR) \log_e (T_2/T_1) + b(T_2 - T_1)$$

$$AR \log_e (V_1/V_2) = a \log_e (T_2/T_1) + b(T_2 - T_1)$$

Graphical Representation. The change of state of a substance may be shown graphically by taking any two of the six variables p, V, T, S, U, H as independent coordinates and drawing a curve to represent the successive values of these two variables as the change proceeds. While any pair may be chosen, there are three systems of graphical representation that are specially useful.

1. p and V. The curve (Fig. 5) represents the simultaneous values of p and V during the change (reversible) from state 1 to state 2. The area between the curve and the axis OV is given by the integral $\int_{V_1}^{V_2} p dV$ and therefore represents the external work W_{12} done by the gas during the change. The area included by a closed cycle represents the work of the cycle (as in the indicator diagram of the steam engine).

2. T and S (Fig. 6). The absolute temperature T is taken as the ordinate; the entropy S as the abscissa. The area between the curve of change of state and the S-axis is given by the integral $\int_{S_1}^{S_2} T dS$, and it therefore represents the heat Q_{12} absorbed by the substance from external sources provided there are no irreversible effects. On the T-S diagram, an isothermal is a straight line, as AB, parallel to the S-axis; a *reversible* adiabatic is a straight line, as CD, parallel to the T-axis.

where V is now the total gas volume and N is the number of molecular weights of gas in the volume V, while M is the molecular weight and MR the universal gas constant. If the amount of gas is expressed as w lb, the preceding equation becomes

$$pV = wRT$$

For all perfect gases, MR in lb-ft is 1546. One pound mol of any perfect gas occupies a volume of 359 cu ft at 32 F and 1 atm.

For many engineering purposes, use of the gas laws is permissible up to pressures of 100 to 200 lb per sq in. if the absolute temperatures are at least twice the critical temperatures. Below the critical temperature, errors introduced by use of the gas laws may usually be neglected up to 15 lb per sq in. pressure although errors of 5 percent are often met when dealing with saturated vapors.

The **van der Waals equation of state,** $p = [BT/(v - b)] - a/v^2$, is a modification of the perfect gas law which is sometimes useful at high pressures. The quantities B, a, and b are constants.

Approximate P-V-T Relations. For most gases, suitable P-V-T data are not available. An approximation useful under such circumstances is based on the observation of van der Waals that in terms of reduced properties most gases approximate a common **reduced equation of state.** The reduced quantities are the actual ones divided by the corresponding critical quantities, *e.g.*, the reduced temperature $T_R = T_{\text{actual}}/T_{\text{critical}}$, the reduced volume $v_R = v_{\text{actual}}/v_{\text{critical}}$, the reduced pressure $p_R = p_{\text{actual}}/p_{\text{critical}}$. The gas laws may be made to apply to any non-perfect gas by the introduction of a correction factor μ

$$pV = \mu NMRT$$

When the gas laws apply, $\mu = 1$ and on a molal basis $\mu = pV/MRT$. If on a plot of μ versus p_R lines of constant T_R are drawn, for different substances these are found to fall in narrow bands. Single T_R lines may be drawn to approximately represent the various bands. This has been done in Figs. 3 and 4. The first chart is for low ranges of p_R and T_R and is based on data for hydrocarbons above methane. The second for high ranges of p_R and T_R is based mainly on hydrogen, nitrogen, and oxygen. To use the charts, only the critical pressure and temperature of the gas need be known.

Example. Find the volume of 1 lb of steam at 5,500 lb abs and 1200 F (by steam tables, $v = 0.1516$ cu ft per lb).

For water, critical temperature = 705.4 F; critical pressure = 3,206.4 lb per sq in. abs; reduced temp = 1660/1165 = 1.43; reduced pressure = 5,500/3206.4 = 1.72 μ (see Fig 3) = 0.83. $v = 0.83 \dfrac{(1546)(1660)}{(18)(5500)(144)} = 0.140$ cu ft. Error = 100(0.152 − 0.149)/0.152 ≐ 1.7 percent. If the gas laws had been used, the error would have been 17 percent.

For gases not conforming to these charts, satisfactory approximations may be obtained by using so-called **pseudo constants** empirically chosen.

Pseudo-critical Constants

Gas	T_c', deg K	p_c' atm
Helium	8.3	10.3
Hydrogen	41.3	20.8
Neon	52.3	33.9

If the cycle is traversed in the reverse sense, $Q_{43} = wART_0 \log_e (V_3/V_4)$ is the heat absorbed from the cold body (brine), and the ratio $Q_{43}: A(W) = T_0:(T - T_0)$ is the **coefficient of performance** of the refrigerating machine.

Stirling and Ericsson Cycles. In the Stirling air engine (Fig. 9), the adiabatics of the Carnot cycle are replaced by constant-volume curves; in the Ericsson engine, by constant-pressure curves. By the use of a regenerator, the heat Q_{23} rejected during the operation 23 is stored and is given back to the medium during the operation 41. In the ideal case, $Q_{23} = Q_{41}$, hence the heat absorbed from the *source is* $Q_{12} = wART \log_e V_2/V_1$, *as in the Carnot* cycle, and the efficiency is identical with that of the Carnot cycle.

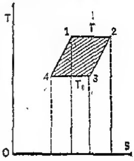

Fig. 9.—Stirling Cycle.

Air engines of the Stirling and Ericsson type, in which the medium is separated from the furnace by a metal wall, have been failures, and have been replaced by the internal-combustion type, in which *the air comes into direct contact with the fuel inside* of the working cylinder. The rapid chemical action supported by the medium itself makes possible the rapid heating of large quantities of gas to a very high temperature. By proper cooling of the outside surface of the metal walls, the deterioration of the metal is prevented even at high temperatures.

The ideal cycles usually employed for internal-combustion engines may be classified in two groups: (1) Explosive—*Otto.* (2) Non-explosive—*Diesel, Joule.*

The Otto Cycle (Fig. 10). Isentropic compression 12 is followed by ignition and *rapid heating at constant volume,* 23. This is followed by isentropic expansion, 34. Assuming constant specific heats the following relations hold:

$$\frac{T_2}{T_1} = \frac{T_3}{T_4} = \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} = \left(\frac{p_3}{p_4}\right)^{\frac{k-1}{k}} = \left(\frac{V_1}{V_2}\right)^{k-1}$$

$$Q_{23} = wc_v(T_3 - T_2)$$

$$(W) = JQ_{23}[1 - (T_1/T_2)] = Jwc_v(T_3 - T_4 - T_2 + T_1)$$

$$\text{Efficiency} = 1 - \frac{T_1}{T_2} = 1 - \left(\frac{V_2}{V_1}\right)^{k-1} = 1 - \left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}}$$

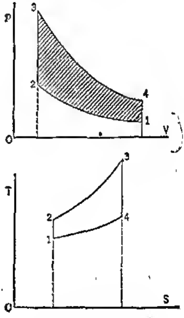

Fig. 10.—Otto Cycle.

If the compression and expansion curves are polytropics with the same value of n, replace k by n in the first relation above. In this case,

$$(W) = [(p_3V_3 - p_4V_4) - (p_2V_2 - p_1V_1)]/(n-1) = wR(T_3 - T_4 - T_2 + T_1)/(n-1)$$

The **mean effective pressure** of the diagram is given by

$$p_m = ap_1[(p_3/p_2) - 1]$$

where a has the values given in the following table.

mixture made up of gases a, b, c, etc., the pseudo-critical constants having been determined, the gaseous mixture is handled on the μ charts as if it were a single pure gas.

Perfect Gas Mixtures. Let V denote the total volume of the mixture, w_1, w_2, w_3 . . . the weights of the constituent gases, R_1, R_2, R_3 . . . the corresponding gas constants, and R_m the constant for the mixture. The partial pressures of the constituents, *i.e.*, the pressures that the constituents would have if occupying the total volume V, are $p_1 = w_1R_1T/V$, $p_2 = w_2R_2T/V$, etc.

According to Dalton's law, the **total pressure** p **of the mixture** is the sum of the partial pressures; *i.e.*, $p = p_1 + p_2 + p_3 + \cdots$. Let $w = w_1 + w_2 + w_3 + \cdots$ denote the total weight of the mixture; then $pV = wR_mT$ and $R_m = \Sigma(w_iR_i)/w$. Also $p_1/p = w_1R_1/wR_m$, $p_2/p = w_2R_2/wR_m$, etc.

Let V_1, V_2, V_3 . . . denote the volumes that would be occupied by the constituents at pressure p and temperature T (these are given by the volume composition of the gas). Then $V = V_1 + V_2 + V_3 + \cdots$ and the apparent molecular weight m_m of the mixture is $m_m = \Sigma(w_iV_i)/V$. Then $R_m = 1546/m_m$. The subscript i denotes an individual constituent.

Volume of 1 lb at 32 F and atm pressure $= 359/m_m$.

Weight of 1 cu ft at 32 F and atm pressure $= 0.002788m_m$.

The specific heats of the mixture are, respectively,

$$c_p = \Sigma(w_ic_{pi})/w, \qquad c_v = \Sigma(w_ic_{vi})/w$$

Internal Energy, Enthalpy, and Entropy. If a perfect gas with constant specific heats changes from an initial state p_1, V_1, T_1, to a final state p_2, V_2, T_2, the following equations hold:

$$U_2 - U_1 = wc_v(T_2 - T_1) = A(p_2V_2 - p_1V_1)/(k - 1)$$

$$H_2 - H_1 = wc_p(T_2 - T_1) = Ak(p_2V_2 - p_1V_1)/(k - 1)$$

$$S_2 - S_1 = w\left(c_v \log_e \frac{T_2}{T_1} + AR \log_e \frac{V_2}{V_1}\right) = w\left(c_p \log_e \frac{T_2}{T_1} - AR \log_e \frac{p_2}{p_1}\right)$$

$$= w\left(c_p \log_e \frac{V_2}{V_1} + c_v \log_e \frac{p_2}{p_1}\right)$$

In general, the energy per unit weight is $u = c_vT + u_0$,

the enthalpy is $h = c_pT + h_0$,

and the entropy is $s = c_v \log_e T + AR \log_e v + s_0$

$= c_p \log_e T - AR \log_e p + s'_0 = c_p \log_e v + c_v \log_e p + s''_0$

The two fundamental equations for perfect gases are

$$dq = c_vdT + Apdv, \qquad dq = c_pdT - Avdp$$

Special Changes of State for Perfect Gases

(Specific heats assumed constant)

In the following formulas, the subscripts 1 and 2 refer to the initial and final states, respectively.

1. Constant Volume: $p_2/p_1 = T_2/T_1$.

$$Q_{12} = U_2 - U_1 = wc_v(t_2 - t_1) = AV(p_2 - p_1)/(k - 1).$$

$$W_{12} = 0. \qquad s_2 - s_1 = wc_v \log_e(T_2/T_1).$$

2. Constant Pressure: $V_2/V_1 = T_2/T_1$.

$$W_{12} = p(V_2 - V_1) = wR(t_2 - t_1).$$

$$Q_{12} = wc_p(t_2 - t_1) = AkW_{12}/(k - 1).$$

$$s_2 - s_1 = wc_p \log_e(T_2/T_1).$$

effected is best shown on the T-S plane (Fig. 14). With single-stage compression, 12 represents the compression from p_1 to p_2, and if the constant-pressure line 23 is drawn cutting the isothermal through point 1 in point 3, the area $1'1233'$ represents the work W. When two stages are used, 14 represents the compression from p_1 to an intermediate pressure p'; 45 cooling at constant pressure in the intercooler between the cylinders, and 56 the compression in the second stage. The area under 14563 represents the work of the two stages and the area 2456 the saving effected by compounding. This saving is a

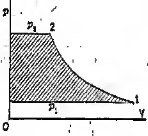

FIG. 13.

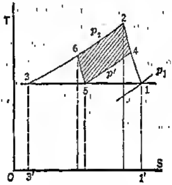

FIG. 14.

Air-compressor Cycle.

maximum when $T_4 = T_6$, and this is the case when the intermediate pressure p' is given by $p' = \sqrt{p_1 p_2}$. See p. 1649

The total work in two-stage compression is

$$-np_1V_1[(p'/p_1)^{(n-1)/n} + (p_2/p')^{(n-1)/n} - 2]/(n-1).$$

Vapors

General Characteristics of Vapors. Let a gas be compressed at constant temperature; then, provided this temperature does not exceed a certain critical value, the gas begins to liquefy at a definite pressure, which depends upon the temperature. At the beginning of liquefaction, a unit weight of gas will also have a definite volume v_g, depending on the temperature. In Fig. 15, AB represents the compression and the point B gives the **saturation** pressure and volume. If the compression is continued, the pressure remains constant with the temperature, as indicated by BC, until at C the substance is in the liquid state, with the volume v_f.

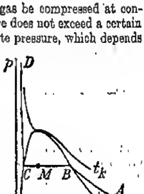

FIG. 15.

The curves v_f and v_g, giving the volumes for various temperatures at the end and beginning of liquefaction, respectively, may be called the **limit curves**. A point B on curve v_g represents the state of **saturated vapor**; a point C on the curve v_f represents the liquid state; and a point M between B and C represents a mixture of vapor and liquid of which the part $x = MC/BC$ is vapor and the part $1 - x = BM/BC$ is liquid. The ratio x is called the **quality of the mixture.** The region between the curves v_f and v_g is thus the region of liquid and vapor mixtures. The region to the right of

4. **Reversible Adiabatic. Isentropic:** $p_1V_1^k = p_2V_2^k$.

$T_2/T_1 = (V_1/V_2)^{k-1} = (p_2/p_1)^{(k-1)/k} = 1/(Y+1)$.

$$AW_{12} = U_1 - U_2 = wc_v(t_1 - t_2). \qquad Q_{12} = 0. \qquad s_2 - s_1 = 0.$$

$$W_{12} = (p_1V_1 - p_2V_2)/(k-1) = p_1V_1[1 - (p_2/p_1)^{(k-1)/k}]/(k-1)$$

$$= p_1V_1\frac{Y}{Y+1}/(k-1) = p_2V_2Y/(k-1)$$

For values of Y, see Table 17.

5. **Polytropic.** This name is given to the change of state which is represented by the equation $pV^n = \text{const.}$ A polytropic curve usually represents actual expansion and compression curves in motors and air compressors for pressures up to a few hundred pounds. By giving n different values and assuming specific heats constant, the preceding changes may be made special cases of the polytropic change, thus,

for $n = 1$,	$pv = \text{const.}$	isothermal
$n = k$,	$pv^k = \text{const.}$	isentropic
$n = 0$,	$p = \text{const.}$	constant pressure
$n = \infty$,	$v = \text{const.}$	constant volume

For a polytropic change of a perfect gas (for which c_v is constant), the specific heat is given by the relation $c_n = c_v(n-k)/(n-1)$; hence for $1 < n < k$, c_n is negative. This is approximately the case in air compression up to a few hundred pounds pressure. The following are the principal formulas: $p_1V_1^n = p_2V_2^n$. $\quad T_2/T_1 = (V_1/V_2)^{n-1} = (p_2/p_1)^{(n-1)/n}$.

$$W_{12} = (p_1V_1 - p_2V_2)/(n-1) = p_1V_1[1 - (p_2/p_1)^{(n-1)/n}]/(n-1).$$

$$Q_{12} = wc_n(t_2 - t_1).$$

$$AW_{12}\!:U_2 - U_1\!:Q_{12} = k - 1\!:1 - n\!:k - n$$

The quantity $Y = (p_1/p_2)^{(k-1)/k} - 1$ occurs frequently in calculations for perfect gases. Values of this quantity are given in Table 17 (condensed

Table 17. Values of Y for Normal Air and Perfect Diatomic Gases

$Y = (p_1/p_2)^{0.283} - 1$

$u_{fg} = u_g - u_f$ = increase of internal energy during vaporization.
$s_{fg} = s_g - s_f = h_{fg}/T$ = increase of entropy during vaporization.
Apv_{fg} = work performed during vaporization.

The energy equation applied to the vaporization process is

$$h_{fg} = u_{fg} + Apv_{fg}$$

The properties of a unit weight of a mixture of liquid and vapor of quality x are given by the following expressions.

$$v = v_f + xv_{fg} \qquad u = u_f + xu_{fg}$$
$$h = h_f + xh_{fg} \qquad s = s_f + xs_{fg}$$

Tables of superheated vapor usually give values of v, h, and s per unit weight. The internal energy u per unit weight can be found from the equation

$$u = h - Apv$$

or with p in lb per sq in.

$$u = h - 0.1852pv$$

Charts for Saturated and Superheated Vapors

Certain properties of vapor mixtures and superheated vapors may be shown graphically by means of charts. Such charts show the behavior of vapors and have a practical application in the solution of certain problems.

1. **Temperature-entropy Chart.** Figure 16 shows the temperature-entropy chart for water vapor. The liquid curve is obtained by plotting corresponding values of T and s_f, and the saturation curve by plotting values of T and s_g. The values are taken from Tables 20 and 21. The two curves merge into each other at the critical temperature T = 1165.1 R. Between these two curves, constant pressure lines are also lines of constant temperature; but at the saturation curve the constant pressure lines show a sharp break with rising temperature. The constant quality lines x = 0.2, 0.4, etc., are equally spaced between the liquid and saturation curves.

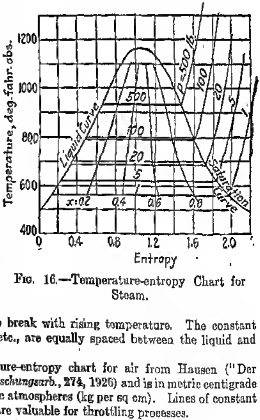

FIG. 16.—Temperature-entropy Chart for Steam.

Figure 17 is a temperature-entropy chart for air from Hausen ("Der Thomson-Joule-Effekt," *Forschungsarb.*, **274**, 1926) and is in metric centigrade units; pressures are in metric atmospheres (kg per sq cm). Lines of constant enthalpy are included and are valuable for throttling processes.

Figure 18 shows a temperature-entropy chart for isobutane. The form of the saturation curve is worthy of note. In the case of water vapor, this curve has a negative slope throughout; but in the case of isobutane, the curve has a positive slope except near the critical temperature. In the case of water

In the case of internal generation of heat through friction, as in steam turbines, the increase of entropy is given by $\int_{T_1}^{T_2} \frac{dQ'}{T}$ (see p. 307) and the area under the curve represents the heat Q' thus generated. In this case, an adiabatic is *not* a straight line parallel to the T-axis.

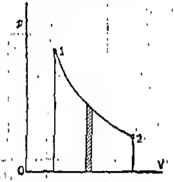

FIG. 5.

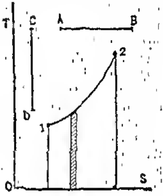

FIG. 6.

3. H and S. In the system of representation devised by Dr. Mollier, the enthalpy H is taken as the ordinate and the entropy S as the abscissa. If on this diagram (Fig. 7) a line of constant pressure, as 12, be drawn, the heat absorbed during the change at constant pressure is given by $Q_{12} = H_2 - H_1$, and this is represented by the line segment 23. The **Mollier diagram** is specially useful in problems that involve the flow of fluids, throttling, and the action of steam in turbines. A Mollier diagram for steam is given on p. 326, and for ammonia on p. 340.

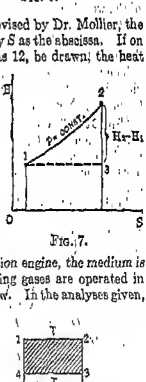

FIG. 7.

Ideal Cycles with Perfect Gases

Gases are used as heat mediums in several important types of motors. In air compressors, air engines, and air refrigerating machines, atmospheric air is the medium. *In the internal-combustion engine, the medium is* a mixture of products of combustion. Motors using gases are operated in certain well-defined cycles, which are described below. In the analyses given, ideal conditions that cannot be attained by actual motors are assumed. However, conclusions derived from such analyses are usually approximately valid for the modified actual cycle.

In the following, the subscripts 1, 2, 3, etc., refer to corresponding points shown in the figures. The work of the cycle is denoted by (W) and the net heat absorbed by (Q).

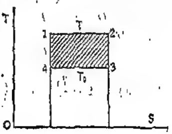

FIG. 8.—Carnot Cycle.

Carnot Cycle. The Carnot cycle (Fig. 8) is of historic interest. It consists of two isothermals and two isentropics. The heat absorbed along the upper isothermal 12 is $Q_{12} = wART \log_e (V_2/V_1)$, and the heat transformed into work, represented by the cycle area, is $A(W) = Q_{12}[1 - (T_0/T)]$.

Hence,
$$(W) = wR(T - T_0) \log_e (V_2/V_1)$$

Following a constant entropy line from the point 240 lb, 580 F, it is found that this line intersects the line $p = 60$ lb on the saturation curve and that the value of h at the point of intersection is 1177.6 Btu. Hence the steam in the second state is just saturated, and the decrease in enthalpy is $1308.5 - 1177.6 = 130.9$ Btu.

3. **Pressure-enthalpy Chart.** For refrigeration media it is convenient to use pressure and enthalpy as the variables to be plotted. Such a chart for ammonia is shown in Fig. 21, p. 340.

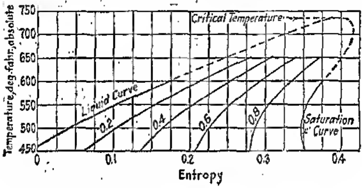

FIG. 18.—Temperature-entropy Chart for Isobutane.

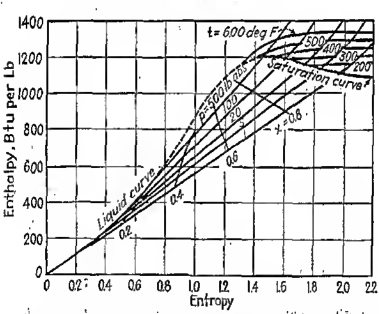

FIG. 19.—Enthalpy-entropy Chart for Steam.

Changes of State. Superheated Vapors and Mixtures of Liquid and Vapor

Isothermal. In the only important cases, the fluid is a mixture of liquid and vapor in both initial and final states.

$t =$ const. $\quad p =$ const. $\quad x_1, x_2 =$ initial and final qualities

$$Q_{12} = wh_{fg}(x_2 - x_1). \qquad U_2 - U_1 = wu_{fg}(x_2 - x_1)$$

$$W_{12} = wpv_{fg}(x_2 - x_1). \qquad S_2 - S_1 = Q_{12}/T$$

Constant Pressure. If the fluid is a mixture at the beginning and end of the change, the constant pressure change is also isothermal. If the initial

	$p_2/p_1 = 3$	4	5	6	8	10	12	14	16
($n = 1.4$)...........	$a = 1.70$	1.94	2.13	2.31	2.02	2.88	3.10	3.31	3.50
($n = 1.3$)...........	$a = 1.69$	1.92	2.11	2.28	2.57	2.81	3.03	3.22	3.39
($n = 1.2$)...........	$a = 1.68$	1.90	2.08	2.25	2.51	2.74	2.94	3.12	3.27

The Diesel Cycle. In the Diesel oil engine, air is compressed to a high pressure. Fuel is then injected into the air and, as the temperature is above the ignition point, burns at nearly constant pressure (23, in Fig. 11). Isentropic expansion of the products of combustion is followed by exhaust and suction of fresh air, as in the Otto cycle.

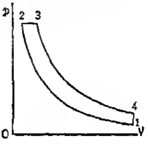

FIG 11.—Diesel Cycle.

The work obtained is

$$(W) = Jw[c_p(T_3 - T_2) - c_v(T_4 - T_1)]$$

and the efficiency of the ideal cycle is

$$1 - [(T_4 - T_1)/k(T_3 - T_2)]$$

The Joule cycle (Fig. 12) consists of two isentropics and two constant-pressure lines. The following relations hold:

$$V_3/V_2 = V_4/V_1 = T_3/T_2 = T_4/T_1$$

$$\frac{T_2}{T_1} = \frac{T_3}{T_4} = \left(\frac{V_1}{V_2}\right)^{k-1} = \left(\frac{V_4}{V_3}\right)^{k-1} = \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}}$$

$(W) = Jwc_p(T_3 - T_2 - T_4 + T_1)$. Efficiency $= (W)/JQ_{23} = 1 - (T_1/T_2)$

For the use of the Joule cycle in refrigeration, see p. 349.

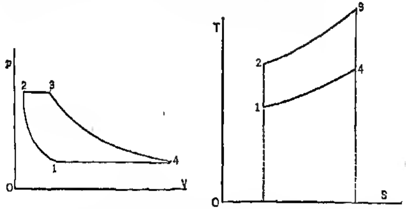

FIG. 12.—Joule Cycle.

Air Compression. It is assumed that the compressor works under ideal reversible conditions without clearance and without friction losses and that the changes are over ranges where the gas laws are applicable. Where the gas laws cannot be used, analysis in terms of μ charts (p. 311) is convenient. If the compression from p_1 to p_2 (Fig. 13) follows the law pV^n = const., the work represented by the indicator diagram is

$$-W = n(p_2V_2 - p_1V_1)/(n - 1) = np_1V_1[(p_2/p_1)^{(n-1)/n} - 1]/(n - 1).$$

The temperature at the end of compression is given by $T_2/T_1 = (p_2/p_1)^{(n-1)/n}$. The work W is smaller the smaller the value of n, and the purpose of the water jacket is to reduce n from the isentropic value 1.4. Under usual working conditions, n is about 1.3.

When the pressure p_2 is high, it is advantageous to divide the process into two or more stages and cool the air between the cylinders. The saving

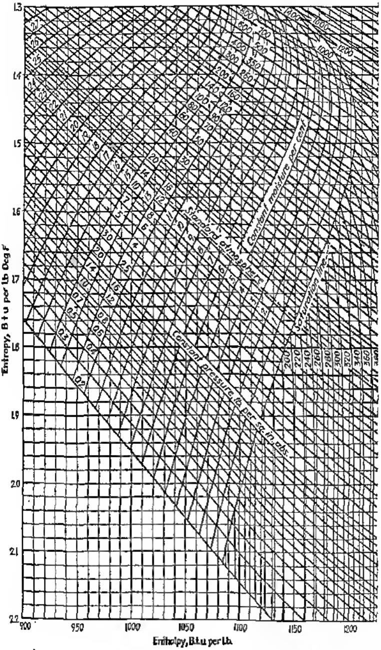

Fig. 20.—Enthalpy-

curve v_g is the region of **superheated vapor**. The curve v_g dividing these regions represents the so-called **saturated vapor**.

For saturated vapor or a **mixture of vapor and liquid**, the pressure is a function of the temperature **only**, and the **volume** of the mixture depends upon the temperature and quality x. That is, $p = f(t)$, $v = F(t, x)$.

For the vapor in the superheated state, the volume depends on pressure and temperature [$v = F_1(p, t)$], and these may be varied independently.

Critical State. If the temperature of the gas lies above a definite temperature t_c called the **critical temperature**, the gas cannot be liquefied by compression alone. The saturation pressure corresponding to t_c is the **critical pressure** and is denoted by p_c. At the critical state, the limit curves v_f and v_g merge; hence for temperatures above t_c, it is impossible to have a mixture of vapor and liquid. Table 18 gives the critical data for various gases; also the boiling temperature t_b corresponding to atmospheric pressure.

Thermal Properties of Saturated Vapors and of Vapor and Liquid Mixtures

Notation:

v_f = volume in cu ft of 1 lb of saturated liquid.
v_g = volume in cu ft of 1 lb of saturated vapor.
c_f = specific heat of saturated liquid.
c_g = specific heat of saturated vapor.
h_f, h_g = specific enthalpy of saturated liquid and vapor, respectively.
u_f, u_g = specific internal energy of saturated liquid and vapor, respectively.
s_f = specific entropy of saturated liquid.
s_g = specific entropy of saturated vapor.
$v_{fg} = v_g - v_f$ = increase of volume during vaporization.
$h_{fg} = h_g - h_f$ = heat of vaporization, or heat required to vaporize 1 lb of liquid at constant pressure and temperature.

r may be used for h_{fg} when several heats of vaporization (as r_1, r_2, r_3, etc.) are under consideration.

Table 20. Properties of Saturated Steam

(From Keenan and Keyes, "Thermodynamic Properties of Steam")

vapor, therefore, isentropic expansion of dry vapor (s = const) will be accompanied by condensation, isentropic compression by superheating. For isobutane, in the region where the saturation curve has the positive slope, the conditions are reversed; isentropic expansion is accompanied by superheating, isentropic compression by condensation.

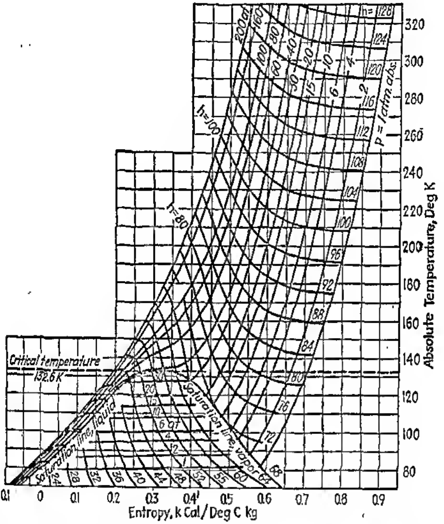

FIG. 17.—Temperature-entropy Chart for Air. (From Hausen, "Der Thomson-Joule Effekt," *Forschungsarbeiten*, 274, 1926.)

2. **Enthalpy-entropy Chart (Mollier Chart).** In this chart, the enthalpy h is taken as the ordinate and entropy as the abscissa. Figure 19 shows a Mollier chart for water vapor. A large-scale chart (Fig. 20) covering only the region near the saturation curve is shown on pp. 326 and 327.

The following examples illustrate the use of the Mollier chart.

1. Steam enters a superheater at a pressure of 240 lb containing 2 percent water. It leaves the superheater at a temperature of 580 F. Required the heat per pound of steam to effect this change.

The initial and final points are located on the Mollier chart. From the enthalpy scale, $h_1 = 1184.2$ and $h_2 = 1308.5$; therefore $q_{12} = 1308.5 - 1184.2 = 124.3$ B.t.u.

2. Steam at $p = 240$ lb, $t = 580$ F expands isentropically to a pressure of 60 lb. Required the final condition of the steam and the decrease in enthalpy.

state is in the mixture region and the final state is that of a superheated vapor, the following are the equations for Q_{12}, etc. Let h_2, u_2, v_2, and s_2 be the properties of 1 lb of superheated vapor in the final state 2: then

$$Q_{12} = w(h_2 - h_1), \qquad h_1 = h_{f1} + x_1 h_{fg1}$$
$$U_2 - U_1 = w(u_2 - u_1), \qquad u_1 = u_{f1} + x_1 u_{fg1}$$
$$S_2 - S_1 = w(s_2 - s_1), \qquad s_1 = s_{f1} + x_1 s_{fg1}$$
$$W_{12} = wp(v_2 - v_1), \qquad v_1 = v_{f1} + x_1 v_{fg1}$$

Constant Volume. Since v_f the liquid volume is nearly constant,

$$x_1 v_{fg1} = x_2 v_{fg2}$$
$$x_2 = x_1 v_{fg1}/v_{fg2}, \qquad \text{or} \qquad x_2 = x_1 v_{g1}/v_{g2} \text{ approx}$$
$$Q_{12} = U_2 - U_1 = w(u_2 - u_1). \qquad W_{12} = 0$$

Isentropic. $s = \text{const.}$

If the fluid is a mixture in the initial and final states,

$$s_{f1} + x_1 s_{fg1} = s_{f2} + x_2 s_{fg2}$$

If the initial state is that of superheated vapor,

$$s_1 = s_{f2} + x_2 s_{fg2}$$

in which s_1 is read from the table of superheated vapor. The final value x_2 is determined from one of these equations, and the final energy u_2 is then $u_{f2} + x_2 u_{fg2}$. $\quad Q_{12} = 0. \quad W_{12} = J(U_1 - U_2) = Jw(u_1 - u_2)$.

For water vapor, the relation between p and v during an isentropic change may be represented approximately by the equation $pv^n = \text{const}$. The exponent n is not constant, but varies with the initial quality and initial pressure, as shown in Table 19.

Table 19. Values of n (Water Vapor)

Initial quality	Initial pressure, lb per sq in. abs											
	20	40	60	80	100	120	140	160	160	200	220	240
1.00	1.131	1.132	1.133	1.134	1.136	1.137	1.138	1.139	1.141	1.142	1.143	1.145
0.95	1.127	1.128	1.129	1.130	1.131	1.131	1.132	1.133	1.134	1.135	1.136	1.137
0.90	1.123	1.123	1.124	1.124	1.125	1.125	1.126	1.126	1.127	1.127	1.128	1.129
0.85	1.119	1.119	1.119	1.119	1.120	1.120	1.120	1.120	1.120	1.120	1.120	1.121
0.80	1.115	1.115	1.114	1.114	1.114	1.114	1.113	1.113	1.113	1.113	1.112	1.112
0.75	1.111	1.110	1.110	1.109	1.109	1.108	1.107	1.106	1.106	1.105	1.104	1.104

The isentropic expansion of superheated steam is fairly represented by $pv^n = \text{const}$, with $n = 1.315$.

The volume at the end of expansion (or compression) is $V_2 = V_1(p_1/p_2)^{1/n}$, and the external work is

$$W_{12} = (p_1V_1 - p_2V_2)/(n - 1) = p_1V_1[1 - (p_2/p_1)^{(n-1)/n}]/(n - 1).$$

If the initial state is in the region of superheat and the final state in the mixture region, two values of n must be used: $n = 1.315$ for the expansion to the state of saturation, and the appropriate value from the first row of Table 19 for the expansion of the mixture.

Tables of Thermal Properties of Vapors

Tables 20, 21, and 22, abstracted from Keenan and Keyes, "Thermodynamic Properties of Steam," give internationally accepted values which are believed to be correct within very narrow tolerance. They are a representation of the results obtained from an organized body of research and agreed to in a series of international conferences.

Diphenyl $(C_6H_5)_2$ has the following properties (Chipman and Peltier, *Ind. Chem. Eng.*, Nov., 1929, p. 1106): boiling point, 491.5 F; density of the liquid 53 lb per cu ft; density of saturated vapor, 0.242 lb per cu ft; heat of vaporization, 134 Btu per lb: all measured at the boiling point. The vapor pressures (p, lb per sq in. abs) at various temperatures (t, deg F) are as follows:

t	200	250	300	350	400	450	500
p	0.060	0.227	0.701	1.832	4.117	8.638	16.29
t	550	600	650	700	750	800	
p	28.54	47.01	73.55	110.1	158.6	221.0	

Dowtherm is a mixture of diphenyl oxide and diphenyl. It is used as a liquid heating medium at elevated temperatures. Its low vapor pressure permits high temperature without attendant high pressures. Table 24 (Badger, *Ind. Chem.*, Sept., 1937) gives properties of a mixture containing 73.5 percent of diphenyl oxide and 26.5 percent of diphenyl which melts at 53.6 F.

Table 20. Properties of Saturated Steam.—(*Continued*)

Ammonia Vapor. The properties of saturated and superheated ammonia vapor have been determined accurately by the Bureau of Standards (*Circ.*, 142, 1923). The principal properties are given in Tables 25 and 26 and Fig. 21.

In the Bureau of Standards table, the entropy s_f and the heat of the liquid h_f are taken as zero at −40 F instead of at 32 F, as is customary in most tables.

Table 25. Properties of Saturated Ammonia

(h and s are measured from −40 F)

Temp, deg F	Pressure, lb per sq in. abs	Specific volume, cu ft per lb		Enthalpy, Btu			Entropy

Properties of Other Refrigerants. Complete and consistent data are not available on most of the working fluids used for refrigeration. The data presented in this section on refrigerating fluids other than ammonia are, in many cases, not of as high order of accuracy as the values given for steam (see also pp. 1854 to 1857).

120	286.4	0.02836	1.047	179.0	455.0	634.0	0.3576	0.7851	1.1427

For the second vessel,

$$w_1(h_1 - t_2 + 32) = w_2r_2 - (w - w_1)(t_1 - t_2)$$

For the third vessel,

$$w_2(h_2 - t_3 + 32) = w_3r_3 - (w - w_1 - w_2)(t_2 - t_3)$$

For a triple-effect system, $w - w_1 - w_2 = w_0$; hence with w and w_0 known, w_1, w_2, and w_3 can be calculated provided the temperatures and pressures within the vessels are known.

The rate q of heat transfer from steam to boiling fluid in a vessel is given by $q = UA\Delta_0$, in which A is the heating surface in square feet, Δ_0 the difference in temperature between the steam and boiling fluid, and U the over-all coefficient of heat transmission in Btu per sq ft per hr per deg F difference in temperature. The value of U is not the same for the different vessels of a multiple-effect system. From the experiments of Claassen, the ratios for different vessels may be taken as follows:

	1st	2d	3d	4th
Double-effect	1	0.66		
Triple-effect	1	0.70	0.33	
Quadruple-effect	1	0.91	0.75	0.55

The value of U depends on many conditions and is difficult to ascertain with accuracy. Creighton ("Steam Engines," p. 524) suggests the following values for cane-sugar evaporators: first vessel, $U = 385$; second, $U = 300$; third, $U = 205$; fourth, $U = 110$. If the fall of temperature in each effect is the same, the heating surfaces must be made larger in the successive vessels. It is usually considered better practice to keep the heating surface practically the same and make the temperature drops larger in the successive vessels.

The water evaporated per hour per square foot of surface varies considerably with the conditions of operation. Hausbrand gives the following figures as the result of practical experience: Ordinary vertical evaporators, with brass heating tubes 3 ft long and over, evaporate from aqueous solutions with single-effect (double-effect) [triple-effect] {quadruple-effect}, 14.0–16.0 (6.0–7.2) [4.0–5.0] {3.5–4.2} lb per sq ft per hr. With steel tubes, the evaporation is decreased 10 to 15 percent.

Steam Cycles

The Rankine Cycle. The ideal Rankine cycle is generally employed by engineers as a standard of reference for comparing the performance of actual steam engines and steam turbines. Figure 22 shows this cycle on the T-S and p-V planes. AB represents the heating of the water in the boiler, BC represents evaporation (and superheating if there is any), CD the assumed isentropic expansion in the engine cylinder, and DA condensation in the condenser.

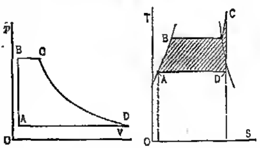

FIG. 22.—Rankine Cycle.

Let h_a, h_b, h_c, h_d represent the enthalpy per pound of steam in the four states A, B, C, and D, respectively. Then the energy transformed into work, represented by the area $ABCD$, is $h_c - h_d$.

Table 26. Properties of Superheated Ammonia

(Condensed from *U. S. B. of S., Circ.* 142, 1923)

v = specific volume in cu ft per lb; h = enthalpy in Btu per lb; s = entropy.

interchange of heat in the heater is

$$w(h_2 - h') = h' - h_{f3}$$

The work done by the bled steam is $w(h_1 - h_2)$ and that by the 1 lb of steam going completely through the turbine is $h_1 - h_3$. Total work $= w(h_1 - h_2) + (h_1 - h_3)$. The heat supplied between feed-water heater and turbine is $(1 + w)(h_1 - h')$. Hence the ideal efficiency of the cycle is

$$e_t = \frac{w(h_1 - h_2) + h_1 - h_3}{(1 + w)(h_1 - h')}$$

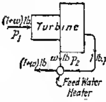

FIG. 24.—Regenerative Feed-water Heating.

For a full discussion of reheating and regenerative cycles, see *Trans. A.S.M.E.*, vol. 45, articles by Wohlenberg, and by Hirschfield and Ellenwood. See also Stodola "Steam and Gas Turbines," Loewenstein's translation, 1927, p. 1310.

Steam Accumulators

A steam accumulator is a device for storing the energy of steam. A large mass of water in a suitable vessel is heated by mixture with steam. When there is an excess of steam, this excess is condensed in the accumulator with a consequent rise of its temperature and pressure. Then during intervals of deficiency of steam, the deficit is drawn from the accumulator. As the pressure in the accumulator drops, the hot water is vaporized at the expense of the stored energy.

The **Rateau** accumulator is principally used to furnish steam to low-pressure turbines. It takes the exhaust from engines working intermittently, as hoisting engines or rolling mill engines, and with sufficient water capacity furnishes a steady supply of steam to the turbine. This accumulator operates at low pressure, and the pressure variation is necessarily small.

The **Ruths** accumulator has its special field in plants that are required to furnish steam for process work; such as plants for sugar factories, pulp and paper mills, textile and chemical industries. It may also be used in plants for the generation of power, solely, and in power and heating stations. The use of the accumulator permits the operation of the boilers under steady conditions at maximum efficiency. The fluctuations in the steam demand due to changes of load are taken care of by the accumulator, leaving the boilers unaffected. In the Ruths accumulator, the pressure may be relatively high, and the change of pressure during operation may be considerable.

For a comprehensive discussion of accumulators, see Stodola "Steam and Gas Turbines," Loewenstein's translation, 1927, p. 863: Taylor and Wettstein, *Mech. Eng.*, Aug. 1925; and Christie, "The Peak-load Problems in Steam Power Stations," *A.S.M.E.*, Dec., 1928.

Accumulator Capacity. The amount of water contained must be sufficient to give the weight of steam required during the discharge period with a predetermined drop of pressure.

Let h_{fg} denote the enthalpy of vaporization, h' the enthalpy of water, W the total weight of water, and p_1, p_2 the initial and final pressures. To evaporate a weight dw, requires an amount of heat $h_{fg}\,dw$ and this is furnished by a drop in temperature of the water. Hence the equation

$$h_{fg}\,dw = W dh'$$

If during the evaporation the pressure drops by dp, then

$T_b/T_a = T_c/T_d = (p_2/p_1)^{(k-1)/k}$. $w = Q/c_p(T_a - T_d)$.

$W = 778Q(T_b - T_a)/T_a$. Horsepower $= W/33{,}000$.

$V_c = wRT_a/144p_1n$. $V_2 = wRT_d/144p_1n$.

For values of $(p_2/p_1)^{(k-1)/k}$ see Table 17.

Vapor-compression Machines. The essential parts of a vapor-compression system are the same as in the system using air, except that the expansion cylinder is replaced by an expansion valve through which the liquefied medium flows from the high-pressure condensing coils to the low-pressure brine coils. The cycle of operation is best shown on the T-S plane (Fig. 26). The point B represents the state of the refrigerating medium leaving the brine coils and entering the compressor. Usually in this state the fluid is nearly dry saturated vapor, *i.e.*, point B is near the saturation curve S_g. BC represents the assumed reversible adiabatic compression, during which the fluid is usually superheated. In the state C, the superheated vapor passes into the cooling coils and is cooled at constant pressure, as indicated by CD, and then condensed at temperature T_2, as shown by DE. The liquid now flows through the expansion valve into the brine coils. This is a throttling process, and the final-state point A is located on the T_1-line in such a position as to make the enthalpy for state A (= area $OHGAA_1$) equal to the enthalpy at E (= area $OHEE_1$). The mixture of liquid and vapor now absorbs heat from the brine and vaporizes, as indicated by AB.

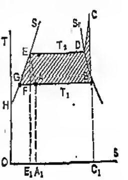

FIG. 26.—Vapor Compression Refrigeration Cycle.

The heat absorbed from the brine, represented by area A_1ABC_1, is

$$Q_1 = h_b - h_a = h_b - h_e$$

The heat rejected to the cooling water, represented by area C_1CDEE_1,

$$Q_2 = h_c - h_e = \text{approximately } c_p(T_c - T_d) + r_2$$

where r_2 denotes the enthalpy of vaporization at the upper temperature T and c_p the specific heat of the superheated vapor. The work that must b supplied per pound of fluid circulated is $W = J(Q_2 - Q_1) = J(h_c - h_b)$. The ratio $JQ_1/W = (h_b - h_e)/(h_c - h_b)$ is sometimes called the **coefficien of performance.**

If Q denotes the heat to be absorbed from the brine per hour, then th weight of fluid circulated per hour is $w = Q/(h_b - h_a)$; or, if B is take on the saturation curve, $w = Q/(h_{g1} - h_{f2})$.

The work per hour is $W = Jw(h_c - h_{g1}) = JQ(h_c - h_{g1})/(h_{g1} - h_{f2})$ ft-lb and the **horsepower required** is $H = Q(h_c - h_{g1})/2544(h_{g1} - h_{f2})$.

If v_{g1} is the volume of the saturated vapor at the temperature T_1 in the brin coils, and n the number of working strokes per minute, the **displacemen volume of the compressor cylinder** is $V = wv_{g1}/60n$.

The values of h_{g1}, h_{f2} in the preceding formulas are found in the tables c saturated vapors. The **enthalpy** h_c of the superheated vapor may be deter mined in the case of ammonia from Table 26 for superheated ammonia.

The carbon dioxide cycle may be investigated by the use of the accom panying chart (Fig. 27). The curves of isentropic compression in the super heat region are bcj, ghm, etc. The boundaries $abcda$ and $aghda$ represent th cycle of the refrigerating machine, the second for the case in which the vapo is superheated at the beginning of compression. Cycles $lbjkl$ and $lgmkl$ appl

Evaporation

Vacuum evaporation, especially of water from solutions of non-volatile solids, is often carried out under less than atmospheric pressure. By this procedure, boiling is obtained at lower temperatures and exhaust steam in closed coils may be used as the heating medium. For many materials, such as milk and sugar, the decomposition and deterioration that occur at elevated temperatures are prevented. For economy, **multiple-effect evaporators** are used. In these, the steam from the boiling solution in the first effect and, in some instances, the condensed steam used in the heating element of the first effect serve as the source of heat to the second effect. The second effect is under a lower pressure than the first and the solution boils at a lower temperature than that prevailing in the first effect. Condensate from the heating coils and steam arising from the solution in the second effect may go to the heating surface in the third effect, and so on through as many as four or more effects. Usually, only three or four effects are used. The solution to be evaporated is usually, but not always, passed through the apparatus concurrent with the passage of the heating medium, *i.e.*, entering at the first and emerging from the last effect.

For details see Hausbrand, "Evaporating, Condensing and Cooling Apparatus" (Scott Greenwood) or Walker, Lewis, McAdams and Gilliland, "Principles of Chemical Engineering" (McGraw-Hill).

In **recompression evaporators** (Prache and Bouillon method), the steam arising from the solution is compressed mechanically and refed to the heating coil. This is a method of restoring to the steam the availability it lost in passage through the evaporator. Most recompression evaporators are single effect (see *Engineering*, Dec., 1916).

Assuming adiabatic operation, enthalpy and material balances may be set up for each effect and for the over-all unit. For simplicity, average boiling temperatures of the solutions passing through each effect are used, and usually it is permissible to assume the enthalpy of the solution at every point equal to the enthalpy of the water plus the solid from which the solution is formed, *i.e.*, no heat effects on mixing. With such simplification, for each effect, the enthalpy of the steam formed in the preceding effect + the enthalpy of the condensate entering from the preceding effect − the enthalpy of the condensate from the heating coil of the effect under consideration = the enthalpy of the steam formed from solution in that effect + the change in enthalpy of the solution passing through that effect. For *dilute* aqueous solutions, the specific heat may be assumed equal to that of water, and the vapor arising from the solution may be assumed saturated instead of superheated as is actually the case. With these additional assumptions, the following approximate energy balances may be formulated.

Let w = weight of liquid introduced in first vessel.

w_1, w_2, w_3, etc. = water evaporated from liquid in first, second, third, etc., vessels.

w_0 = weight of liquid withdrawn from last vessel.

G = weight of steam introduced into first vessel.

t_0 = temperature of liquid entering first vessel.

t_1, t_2, t_3, etc. = mean temperatures of boiling liquid in first, second, third, etc., vessels.

h = enthalpy of steam G, r = latent heat of same.

h_1, h_2, h_3, etc. = enthalpy of vapor in successive vessels.

r_1, r_2, r_3, etc. = latent heats of vapor in successive vessels.

For the first vessel, the energy equation is

$$G(h - t_1 + 32) = w(t_1 - t_0) + w_1r_1$$

when the temperature of the cooling water is so high that the condensing pressure is greater than the critical pressure. In *abcda*, the segment $ab = h_b - h_a$ represents the heat absorbed from the brine and the segment $cd = h_c - h_d$ represents the heat rejected to the cooling water. These quantities may be read directly from the chart.

Figure 28 is a similar chart for Freon.

Hampson-Linde Regenerative Process. The Joule-Thomson effect (see p. 361) has been used by Hampson, Linde, and others for the liquefaction of air and other gases. In the Hampson process (Fig. 29), air is compressed to a pressure of 150 to 200 atm and discharged into a pipe leading to the chamber *c*. The air in its passage to *c* is cooled by water. From *c*, the air passes through an expansion valve into a vessel *d*, in which the pressure is only slightly above atmospheric. The throttling in the expansion valve causes a marked drop in temperature.

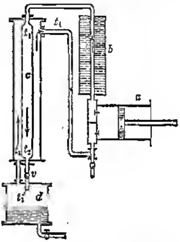

Fig. 29.—Regenerative Refrigeration Process.

The air now passes back to the compressor and in so doing cools the air in *c*. In the actual machine, the countercurrent apparatus, which in the figure is shown as the chamber *c* and the space surrounding it, consists of one or more pipes wound in a succession of flat coils one above the other, over which the return stream flows. By the cooling action of the return current of air, the temperature t_2 gradually sinks, and the temperature t_3 sinks more rapidly. Ultimately t_3 becomes lower than the critical temperature of air (−220 F), and liquefaction begins.

A small Linde liquid-air machine with an output of 20 to 25 lb of liquid air per hour consumes 30 to 40 hp, compresses 3,000 cu ft of air per hour, and has an efficiency of about 8 percent. A laboratory size Hampson machine delivers 2 lb of liquid air per hour and consumes 10 to 12 hp. With a plant of a capacity of at least 30 lb of liquid air per hour, Linde states (*Mech. Eng.*, 46, p. 582) that 1 lb of liquid air can be produced with from 0.9 to 1.6 hp-hr depending on whether double- or single-stage expansion is used.

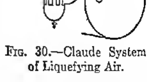

Fig. 30.—Claude System of Liquefying Air.

By the use of the regenerative process, liquid air or other gas may be produced continuously and in relatively large quantities by the simple mechanical process of compression. The necessary lowering of temperature is effected by repeated throttling of the gas, and a second refrigerating medium is not required.

Claude's System of Liquefying Air. Claude has succeeded in liquefying air by direct expansion of the air in a cylinder. A diagram of the apparatus in its simplest form is shown in Fig. 30. Air at a pressure of 25 to 30 atm enters through the central pipe of the interchanger *M*. Part of the air passes into the cylinder

The energy expended on the fluid is $h_c - h_a$; hence the Rankine cycle efficiency is $e_t = (h_c - h_d)/(h_c - h_a)$.

The **steam consumption** of the ideal Rankine engine in pounds per horsepower hour is $N_r = 2544/(h_c - h_d)$. Expressed in pounds per kilowatt-hour, the steam consumption of the ideal Rankine cycle is $3{,}412.7/(h_c - h_d)$.

The performance of an engine is frequently stated in terms of the heat used per hp-hr. For the ideal Rankine engine, this is

$$Q_r = 2544/e_t = 2544(h_c - h_a)/(h_c - h_d)$$

Efficiency of the Actual Engine. Let Q denote the heat transformed into work per pound of steam by the actual engine; then if Q_1 is the heat furnished by the boiler per pound of steam, the thermal efficiency of the engine is $e_t = Q/Q_1$.

The efficiency thus defined is misleading, as it takes no account of the conditions of boiler and condenser pressure, superheat, or quality of steam. It is customary therefore to define the efficiency as the ratio Q/Q_a, where Q_a is the **available heat**, or the heat that could be transformed under ideal conditions. For steam engines and turbines, the Rankine cycle is usually taken as the ideal, and the quantity $Q/Q_a = Q/(h_c - h_d)$ is called the **engine efficiency.** For engines and turbines, this efficiency ranges from 0.50 to 0.85. The engine efficiency e may also be expressed in terms of steam consumed; thus, if N_a is the steam consumption of the actual engine and N_r is the steam consumption of the ideal Rankine engine under similar conditions, then $e = N_r/N_a$.

Example. Suppose the boiler pressure to be 180 lb per sq in. abs, superheat 150 deg, and the condenser pressure 3 in. of mercury. From the steam tables or diagram, the following values are found: $h_c = 1283.3$, $h_d = 942$, $h_a = 82.99$. The available heat is $Q_a = 1283.3 - 942 = 341.3$ Btu, and the thermodynamic efficiency of the cycle is $341.3/(1283.3 - 82.99) = 0.284$. The steam consumption per horsepower-hour is $2546/341.3 = 7.46$ lb, and the heat used per horsepower-hour is $2546/0.284 = 8960$ Btu. If an actual engine working under the same conditions has a steam consumption of 11.4 lb. per hp-hr, its efficiency is $7.46/11.4 = 0.655$, and its heat consumption per horsepower-hour is $8960/0.655 = 13{,}680$ Btu.

Reheating Cycle. Let the steam after expansion from p_1 to an intermediate pressure p_2 (cd, Fig. 23) be reheated at constant pressure p_2, as indicated by de. Then follows the isentropic expansion to pressure p_3, represented by ef.

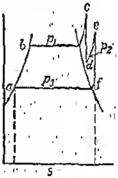

Fig. 23.—Reheating Cycle.

The energy absorbed by 1 lb of steam is $h_c - h_a$ from the boiler, and $h_e - h_d$ from the reheating. The work done is $h_c - h_d + h_e - h_f$. Hence the efficiency of the cycle is

$$e_t = \frac{h_c - h_d + h_e - h_f}{h_c - h_a + h_e - h_d}$$

Bleeding Cycle. In the **regenerative** or bleeding cycle, steam is drawn from the turbine at one or more stages and used to heat the feed water. Figure 24 shows a diagrammatic arrangement for bleeding at one stage. Entering the turbine is $1 + w$ lb, of steam at p_1, t_1, and enthalpy h_1. At the bleeding point w lb at p_2, t_2, h_2 enters the feed-water heater. The remaining 1 lb passes through the turbine and condenser and enters the feed-water heater as water at temperature t_3. Let t' denote the temperature of the water leaving the heater, and h' the corresponding enthalpy of the liquid. Then the equation for the

1. The continuity equation, or material balance,

$$w = \frac{A_1V_1}{v_1} = \frac{A_2V_2}{v_2} \quad \text{or} \quad \frac{dv}{v} = \frac{dA}{A} + \frac{dV}{V}$$

2. The first law or energy balance for steady flow

$$Jq_{12} = Jh_{12} + \frac{V_2^2 - V_1^2}{2g} + X_2 - X_1$$

3. The available energy balance for a steady-flow process

$$v\,dp + \frac{V\,dV}{g} + dF + dX = 0$$

In the processes here discussed, no net external or shaft work is performed. For most actual processes, the third equation cannot be integrated because the actual path is not known. Usually, adiabatic flow is assumed but occasionally the assumption of isothermal conditions may be more nearly correct.

Flow through Orifices and Nozzles. As a compressible fluid passes through a nozzle, drop in pressure and simultaneous increase in velocity result. By assuming the type of flow, *e.g.*, adiabatic, it is possible to calculate from the properties of the fluid the required area for the cross section of the nozzle at any point in order that the flowing fluid may just fill the provided space. From this calculation, it is found that for all compressible fluids the nozzle form must first be converging but eventually, if the pressure drops sufficiently, a place is reached where to accommodate the increased volume due to the expansion the nozzle must become diverging in form. The smallest cross section of the nozzle is called the throat, and the pressure at the throat is the **critical flow pressure** (not to be confused with the previously mentioned critical pressure, p. 321). If the nozzle is cut off at the throat with no diverging section and the pressure at the discharge end is progressively decreased, with fixed inlet pressure, the amount of fluid passing increases until the discharge pressure equals the critical, but further decrease in discharge pressure does not result in increased flow. A similar phenomenon is found for orifices. For any particular gas, the ratio of critical to inlet pressure is approximately constant. For gases, $p_m/p_1 = 0.53$ approximately; for saturated steam, the ratio is about 0.575; and for moderately superheated steam, about 0.55.

FIG. 32.

Formulas for Orifice Computations. The general fundamental relation is given by the energy balance $(V_2^2 - V_1^2)/2g = -Jh_{12}$. Referring to Fig. 32, let section 2 be taken at the orifice, section 3 is somewhat beyond the orifice on the downstream side, and section 1 is before the orifice on the upstream side. Then

$$V_2 = \frac{C\sqrt{2gJ(h_1 - h_2)}}{\sqrt{1 - \left(\frac{A_2}{A_1}\right)^2\left(\frac{v_1}{v_2}\right)^2}}$$

The coefficient of discharge factor C is discussed on p. 1804.

The volume of gas passing is V_2A_2 cu ft per sec, and the weight is $V_2A_2\rho$. For perfect gases, assuming reversible adiabatic expansion through the orifice,

$$\frac{dw}{dp} = \frac{W}{h_{fg}}\frac{dh'}{dp} \qquad \text{or} \qquad w = \int_{p_2}^{p_1} \frac{W}{h_{fg}}\frac{dh'}{dp}dp$$

If in this equation W is taken as the weight of a cubic foot of water, then w obtained from the integral will be the weight of steam generated per cubic foot of water for a drop in pressure p_1 to p_2. Since W, h_{fg}, and h' vary with the temperature (and therefore with the pressure), to perform the indicated integration the expression $(W/h_{fg})(dh'/dp)$ must be expressed as a function of p. The result is the following approximate expression for w, the pressures being in pounds per square inch absolute:

$$w = \tfrac{1}{2}[10 \log (p_1/p_2) + p_1^{1/2} - p_2^{1/2}]$$

For example, let $p_1 = 100$, $p_2 = 80$ lb per sq in. Then

$$w = \tfrac{1}{2}[10 \times 0.09691 + 10 - 8.944] = 1.013 \text{ lb}$$

REFRIGERATION

(See also pp. 1851 to 1881)

Air Refrigeration. When air is used as a medium for refrigeration, the reversed Joule cycle is employed (see p. 319). The refrigerating machine has four essential parts: (1) a compressor in which the air is compressed; (2) a cooling coil surrounded by water; (3) an expansion cylinder; (4) a brine coil. Figure 25 represents ideal p-V and T-S diagrams. Point A represents the state of the air entering the compressor from the brine coil or cold room, AB represents the compression, BC the cooling of the air at constant pressure, CD the expansion of air in the expansion cylinder, and DA the absorption of heat by the air during the passage through the brine coils. In the p-V diagram, $ABEF$ represents the indicator diagram of the compressor, $ECDF$ that of the expansion cylinder. The difference, area $ABCD$, represents the work that must be furnished from external sources. In the T-S diagram, area B_1BCC_1 represents the heat absorbed from the air by the cooling water, area C_1DAB_1, the heat absorbed by the air from the brine, and area $ABCD$ the heat equivalent of the work required to drive the machine. The temperature at point A must be somewhat lower than the brine temperature, the temperature at C somewhat above the temperature of the cooling water. With the open-cycle machine, the lower pressure p_1 is atmospheric pressure; with a closed-cycle machine, as the Allen dense-air machine, p_1 may be 40 to 60 lb and p_2 as high as 200 lb per sq in.

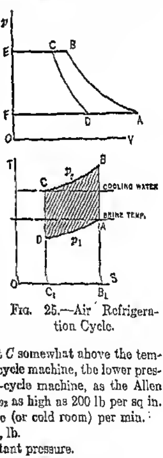

Fig. 25.—Air Refrigeration Cycle.

Let Q = heat in Btu absorbed from brine (or cold room) per min.
- w = weight of air circulated per min, lb.
- c_p = 0.24, specific heat of air at constant pressure.
- W = work required per min, ft-lb.
- V_c = displacement volume of compressor cylinder, cu ft.
- V_e = displacement volume of expansion cylinder, cu ft.
- n = number of working strokes per min.

By assuming (1) the gas laws, (2) constant specific heats, (3) reversible operation, and (4) isentropic compression and expansion, it is found that

express, approximately, the discharge w of saturated steam in terms of A_2 and p_1 as follows:

1. Napier's equation, $w = A_2p_1/70$.
2. Grashof's formula, $w = 0.0165A_2p_1^{0.97}$.
3. Rateau's formula, $w \doteq A_2p_1(16.367 - 0.96 \log p_1)/1000$.

In these formulas, A_2 is to be taken in square inches, p_1 in lb per sq in. Napier's formula is merely convenient as a rough check. Formulas 2 and 3 are applicable to well-rounded convergent orifices, in which case the coefficient of discharge may be taken as 1; *i.e.*, no correction is required. For flow of superheated steam, see also p. 1186.

When the back pressure p_2 is greater than the critical pressure p_m, the velocity and discharge are found most conveniently from the general formulas of flow. From the steam tables (p. 328) or from the Mollier chart (p. 326), find the initial enthalpy h_1 and the enthalpy h_2 after isentropic expansion; also the specific volume v_2 (see Fig. 33). Then

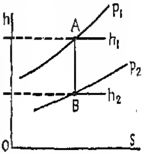

FIG. 33.

$$V_2 = 223.7\sqrt{h_1 - h_2} \qquad \text{and} \qquad w = A_2V_2/v_2$$

The same method is used in the case of steam initially superheated.

Example. Required the discharge through an orifice ½ in. diam of steam at 140 lb per sq in. superheated 110 F, back pressure, 90 lb per sq in.

From the Mollier chart, $h_1 = 1255.7$, and $h_2 = 1214$. Also $v_2 = 5.30$ cu ft

$$V_2 = 223.7\sqrt{1255.7 - 1214} = 1445$$
$$A_2 = 0.1964 \text{ sq in.} = (0.1964/144) \text{ sq ft}$$
$$w = A_2V_2/v_2 = (0.1964/144) \times (1445/5.30) = 0.372 \text{ lb per sec}$$

This calculation assumes ideal conditions, and the results must be multiplied by the correct coefficient of discharge to get actual results.

Flow through Converging-diverging Nozzles. At the throat, or smallest cross section of the nozzle (Fig. 34), the pressure of saturated steam takes the value $p_m = 0.57p_1$. The weight discharged is fixed by the area A_2 of the throat and the initial pressure p_1. For saturated steam, Grashof's or Rateau's formula (see above) may be used. The diverging part of the nozzle permits further expansion to the back pressure p_3, the velocity of the jet meanwhile increasing from $V_m (= V_2)$, the critical velocity at the throat, to V_3 given by the fundamental equation $V_3 = 223.7\sqrt{h_1 - h_3}$.

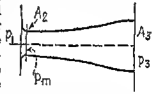

FIG. 34.

The frictional resistances in the nozzle have the effect of decreasing the jet energy $V_3^2/2g$ and correspondingly increasing the enthalpy of the flowing fluid. Thus, if h_3 is the enthalpy in the final state with frictionless expansion, $h'_3(>h_3)$ is the enthalpy when friction is taken into account; hence $(V'_3)^2/2g = J(h_1 - h'_3)$ is less than $V_3^2/2g = J(h_1 - h_3)$. The loss of kinetic energy, in Btu, is $h'_3 - h_3$, and the ratio of this loss to the available kinetic energy, *i.e.* $(h'_3 - h_3)/(h_1 - h_3)$, is denoted by y. For values of y, see p. 358.

The **design of a nozzle for a given discharge** w with pressures p_1 and p_3 is most conveniently effected with the aid of the Mollier chart. Determine p_m, the critical pressure, and h_1, h_m, h_3, assuming frictionless flow. Then

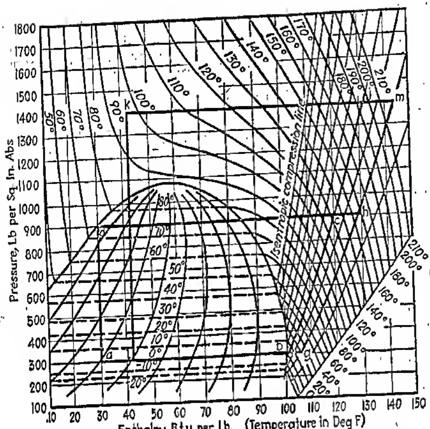

FIG. 27.—Pressure-enthalpy Chart for Carbon Dioxide.

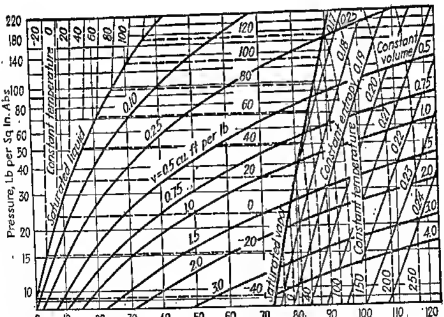

FIG. 28.—Pressure-enthalpy Chart for Freon.

pv^n = const throughout the expansion. With a value of $n = 1.315$, which holds good in the superheat region, the following results are found.

1. Equilibrium expansion	2. Expansion with supersaturation
$t_2 = 228$ F	173.4 F
$v_2 = 19.46$ cu ft	18.245 cu ft
$V = 1612$ fps	1597 fps
$V/v_2 = 82.8$	87.53

In the first case, the velocity is obtained from the usual equation $V = 223.7\sqrt{h_1 - h_2}$, in the second case, from the general equation $V^2/2g = n(p_1v_1 - p_2v_2)/(n - 1)$. The discharge is proportional to the ratio V/v_2; and since $87.53/82.8 = 1.056$, the discharge with supersaturation is 5.4 percent greater than with equilibrium expansion. The difference between the two values of t_2, *viz.*, $228 - 173.4 = 54.6$ deg, is the **undercooling** of the supersaturated steam. The pressure of saturated steam at $t_2 = 173.4$ F is 6.48 lb per sq in. The actual pressure of the undercooled steam at this temperature is 20 lb per sq in. The ratio of these pressures $20/6.48 = 3.09$ is the **degree of supersaturation.**

The effect of supersaturation in turbines is a loss of energy, the amount of which may be 1.5 to 3 percent of the available energy of the steam.

Flow of Wet Steam. When the steam entering a nozzle is wet, the speed of the water particles at exit is not the same as the speed of the stream. Denoting by V the speed of the steam, the speed of the water drops is fV, and f may vary perhaps 0.20 to 0.05 or less, depending on the pressure. The actual velocity V of the steam is greater than the velocity V_0 calculated on the usual assumption that steam and water have the same velocity. If x is the quality of the steam, the ratio of these velocities is

$$V/V_0 = 1/\sqrt{x + f^2(1 - x)}$$

Thus with $x = 0.92$, $f = 0.15$, $V/V_0 = 1.036$. Since the discharge is practically proportional to the steam velocity, the actual discharge in this case is 3.6 percent greater than the discharge computed on the usual assumptions.

Velocity Coefficients. Loss of Energy y. On account of friction losses, the actual velocity V attained by the jet is less than the velocity V_0 calculated under ideal conditions. That is, $V = xV_0$, where x (<1) is a velocity coefficient. The coefficient x is connected with the coefficient y, giving the loss of energy, by the relation, $y = 1 - x^2$.

The elaborate and accurate experiments of the General Electric Co. on turbine nozzles (Warren and Keenan, *Trans. A.S.M.E.*, 48, p. 33) give for convergent nozzles values of x in excess of 0.98, with a corresponding loss of energy $y = 0.025$ to 0.04. For similar nozzles, the experiments of the Steam Nozzles Research Committee (of England) by a different method give values of x around 0.96, or $y = 0.08$. In the case of divergent nozzles, the velocity coefficient may be somewhat lower.

Flow of Fluids in Circular Pipes

(See pp. 264 to 272)

The fundamental equation as previously given, assuming the pipe horizontal, is

$$(VdV/g) + vdp + dF = 0$$

The friction term dF includes not only losses due to frictional flow along the pipe but also those due to fittings, valves, etc., as well as losses occasioned by any enlargement or contraction of the pipe as, for instance, the loss occurring when a fluid passes from a pipe into a tank. For long straight pipes of

D where it expands doing work, and its temperature is thereby lowered. It is then discharged into the liquefier L where it cools the remainder of the compressed air which has entered the tubes of L.

With an expansion cylinder, 1 lb of liquid oxygen of 88 percent purity can be obtained from 0.77 hp-hr of work (*Mech. Eng.*, 46, p. 582).

For a complete account of the liquefaction of gases, see Claude, "Liquid Air, Oxygen and Nitrogen."

FLOW OF COMPRESSIBLE FLUIDS

REFERENCES: Stodola, "Steam and Gas Turbines," Loewenstein's translation, McGraw-Hill. Goodenough, "Principles of Thermodynamics," Van Nostrand. Lucke, "Engineering Thermodynamics," McGraw-Hill. Berry, *Mech. Eng.*, Nov., 1929. Gutermuth, *Z.V.d.I.*, 48. Buchner, *Z.V.d.I.*, 49. Walker, Lewis, McAdams, and Gilliland, "Principles of Chemical Engineering," McGraw-Hill.

Important examples of the flow of compressible fluids are the following: (1) The flow of air and steam through orifices and short tubes or nozzles, as in the steam turbine. (2) The flow of compressed air, steam, and illuminating gas in long mains. (3) The flow of low-pressure gases, as furnace gases in ducts and chimneys or air in ventilating ducts. (4) The flow of gases in moving channels, as in the centrifugal fan.

Notation.

Let A = area of section, sq ft.
C = empirically determined coefficient of discharge.
D = inside diameter of pipe, ft.
$d = 12D$ = inside diameter of pipe, in.
F_{12} = energy expended in overcoming internal and external friction between sections A_1 and A_2.
F' = energy used in overcoming friction, ft-lb per lb of fluid flowing.
f = friction factor.
$g = 32.2$
h = enthalpy, Btu per lb.
$J = 778.3$
$k = c_p/c_v$.
L = equivalent length of pipe, ft.
μ = viscosity, centipoises.
p = pressure of fluid at given section, lb per sq ft abs.
p_m = critical flow pressure.
Q_{12} = heat entering the flowing fluid between sections A_1 and A_2.
R = perfect gas constant.
ρ = density, lb per cu ft.
T = temperature R.
V = mean velocity in ft per sec at the given section.
v = volume per unit weight, cu ft per lb.
w = weight in lb of fluid flowing past a given section per sec.
X = height from center of gravity of flow to a fixed base level, ft.

The cross sections of the tube or channel are denoted by A_1, A_2, etc. (Fig. 31), and the various magnitudes pertaining to these sections are denoted by corresponding subscripts. Thus, at section A_1, the velocity, volume, and pressure are, respectively, V_1, v_1, p_1; at section A_2, they are V_2, v_2, p_2.

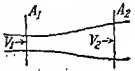

FIG. 31.

Fundamental Equations. In the interpretation of fluid-flow phenomena, three fundamental equations are of importance.

to 0.0054. Babcock has suggested the approximation $f = 0.0027(1 + 3.6/d)$ for steam.

Values of f as a function of pipe surface are given by Fig. 21, p. 266.

For predicting the capacity of a given pipe operating on a chosen fluid with fixed pressure drop, the use of Fig. 37 eliminates the trial-and-error methods usually involved. Figure 38 gives the viscosity of various gases.

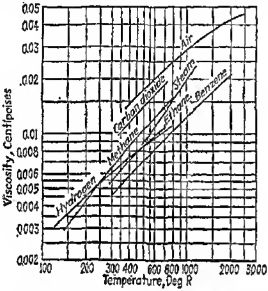

FIG. 38.—Viscosity of Gases.

Example. Air at 68 F is flowing isothermally through a straight standard 1 in. pipe (I.D. = 1.049 in.). The pipe is 200 ft long, the pressure at the pipe inlet is 60 lb per sq in. gage, and the pressure drop through the pipe is 5 lb per sq in. The average density of the air in the pipe is

$$\rho_{avg} = 0.0753\,[(60 + 14.7) + (55 + 14.7)]/2 \times 14.7 = 0.370 \text{ lb per cu ft}$$

$$F' = \frac{(5.0)(144)}{0.370} = 1945 \text{ ft lb/lb}$$

$$D = \frac{1.049}{12} = 0.0875 \text{ ft}$$

$$x = \sqrt{\frac{2(32.2)(0.0875)(0.370)^2(1.945)}{200}} = 2.74$$

μ = 0.018 centipoise (Fig. 38), or (0.018)(0.000672) = 0.0000121 in lb ft sec units.

$$\frac{Dx}{\mu} = \frac{(0.0875)(2.74)}{0.0000121} = 19{,}800 \text{ and from Fig. 37 the corresponding value of } \frac{\rho V}{x} \text{ is } 7.05.$$

$$V = \frac{7.05(2.74)}{0.370} = 52.2 \text{ ft per sec}$$

$$w = AV\rho = \frac{(3.1416)(0.0875)^2}{4}(52.2)(0.370) = 0.116 \text{ lb per sec}$$

Resistances due to fittings, expressed in terms of L/D, are as follows: 90 deg elbows, 1–2½ (3–6) [7–10] in., 30 (40) [50]; 90 deg curves, radius of center line of curve 2–8 pipe diameters, 10; globe valves, 1–2½ (3–6) [7–10] in., 45 (60) [75]; tees, 1–4 in., 60. The resistance in energy units, due to sudden enlargement in a pipe, is approximately $(V_1 - V_2)^2/2g$. For sudden contraction it is $1.5(1 - r)V_2^2/2g(3 - r)$, where $r = A_2/A_1$.

$$V_2 = \frac{C\sqrt{2gp_1v_1\frac{k}{k-1}\left[1-\left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}}\right]}}{\sqrt{1-\left(\frac{A_2}{A_1}\right)^2\left(\frac{p_2}{p_1}\right)^{\frac{2}{k}}}}$$

$$w = \frac{CA_2p_2\sqrt{\frac{2g}{RT_1}\frac{k}{k-1}\left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}}\left[\left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}}-1\right]}}{\sqrt{1-\left(\frac{A_2}{A_1}\right)^2\left(\frac{p_2}{p_1}\right)^{\frac{2}{k}}}}$$

V_1 is often small compared with V_2, and under these conditions the denominators in the preceding equations become approximately equal to unity. For air assuming $R = 53.3$, $k = 1.40$, and V_1 negligible,

$$w = 2.05CA_2p_2\sqrt{(1/T_1)(p_1/p_2)^{0.283}[(p_1/p_2)^{0.283}-1]}$$
$$= 2.05CA_2p_2\sqrt{(1/T_1)(1+Y)Y}$$

Values of Y are given on p. 315.

Although the preceding formulas are generally applicable under the assumed conditions, it must be remembered that irrespective of the value of p_1, p_2 cannot become less than p_m. When p_2 is less than p_m, the flow rate becomes independent of the downstream pressure; for perfect gases,

$$w = CA_2p_1\sqrt{\frac{g}{RT_1}k\left(\frac{2}{k+1}\right)^{(k+1)/(k-1)}}$$

or for air

$$w = 0.53Cp_1\frac{A_2}{\sqrt{T_1}}$$

Where the pressure drop through the orifice is small, the hydraulic formulas (pp. 253, 1803) applicable to incompressible fluids may be employed for gases and other compressible fluids.

In general, the formulas of the preceding section are applicable to nozzles. When so used however, the proper value of the discharge coefficient must be employed. For steam nozzles, this may be as high as 0.94 to 0.96, although for many orifice installations it is as low as 0.50 to 0.60. Steam nozzles constitute a most important type, and calculations for these are best carried out with the aid of a Mollier or similar chart.

Formulas for Discharge of Steam. When the back pressure p_2 is less than the critical pressure p_m, the discharge depends upon the area of orifice A_2 and reservoir pressure p_1. There are three formulas widely used to

Table 31. Values of $p^{0.97}$ for Use in Grashof's Formula

p	$p^{0.97}$	p	$p^{0.97}$	p	$p^{0.97}$	p	$p^{0.97}$
15	13.8	50	44.5	110	95.5	225	191.2
20	18.3	55	48.8	120	104.0	250	212.0
25	22.7	60	53.1	130	112.4	275	232.0
30	27.1	70	61.6	140	120.7	300	253.0
35	31.5	80	70.1	150	129.1		
40	35.8	90	78.6	175	150.0		
45	40.1	100	87.1	200	170.6		

as a product, carbon dioxide, CO_2; the combustion of hydrogen gives water, H_2O.

Combustion of Gaseous and Liquid Fuels

Combustion Equations. The approximate molecular weights of the important elements and compounds entering into combustion calculations are:

Gas	H_2	O_2	N_2	CO	CO_2	H_2O	CH_4	C_2H_4	C_2H_6O
Molecular weight	2	32	28	28	44	18	16	28	46

For the elements C and H, the equations of complete combustion are

$$\begin{cases} C + O_2 = CO_2 \\ 12\text{ lb} + 32\text{ lb} = 44\text{ lb} \end{cases} \qquad \begin{matrix} H_2 + \tfrac{1}{2}O_2 = H_2O \\ 2\text{ lb} + 16\text{ lb} = 18\text{ lb} \end{matrix}$$

For a combustible compound, as CH_4, the equation may be written

$$CH_4 + x\cdot O_2 = y\cdot CO_2 + z\cdot H_2O$$

Taking, as a basis, 1 molecule of CH_4 and making a balance of the atoms on the two sides of the equation, it is seen that

$$y = 1, \quad z = 2; \quad 2x = 2y + z, \quad \text{or } x = 2$$

Hence
$$\begin{cases} CH_4 + 2O_2 = CO_2 + 2H_2O \\ 16\text{ lb} + 64\text{ lb} = 44\text{ lb} + 36\text{ lb} \end{cases}$$

The coefficients in the combustion equation give the combining volumes of the gaseous components. Thus, in the last equation 1 cu ft of CH_4 requires for combustion 2 cu ft of oxygen and the resulting gaseous products of combustion are 1 cu ft of CO_2 and 2 cu ft of H_2O. The coefficients multiplied by the corresponding molecular weights give the combining weights. These are conveniently referred to 1 lb of the fuel. In the combustion of CH_4, for example, 1 lb of CH_4 requires $64/16 = 4$ lb of oxygen for complete combustion and the products are $44/16 = 2.75$ lb of CO_2 and $36/16 = 2.25$ lb of H_2O.

Air Required for Combustion. The composition of air is approximately 0.232 O_2 and 0.768 N_2 by weight, or 0.21 O_2 and 0.79 N_2 by volume. For exact analyses, it may be necessary sometimes to take account of the water vapor mixed with the air, but ordinarily this may be neglected.

The minimum weight of air required for the combustion of 1 lb of a fuel is the weight of oxygen required, as found from the combustion equation, divided by 0.232. Likewise, the minimum volume of air required for the combustion of 1 cu ft of a fuel gas is the volume of oxygen divided by 0.21. For example, in the combustion of CH_4 the weight of air required per pound of CH_4 is $4/0.232 = 17.24$ lb and the volume of air per cubic foot of CH_4 is $2/0.21 = 9.52$ cu ft. Ordinarily, more air is provided than is required for complete combustion. Let a denote the minimum weight required and xa the weight of air admitted; then $x - 1$ is the **excess coefficient.**

Products of Combustion. The products arising from the complete combustion of a fuel are CO_2, H_2O, and, if sulphur is present, SO_2. Accompanying these are the nitrogen brought in with the air and the oxygen in the excess of air. Hence the products of complete combustion are principally CO_2, H_2O, N_2, and O_2. The presence of CO indicates incomplete combustion. The composition of the products of combustion is readily calculated from the combustion equations, as shown by the following illustrative example.

Example. A producer gas having the volume composition given is burned with 20 percent excess of air; required the volume composition of the exhaust gases.

$$V_m = 223.7\sqrt{h_1 - h_m}, \quad \text{and} \quad V'_3 = 223.7\sqrt{(1-y)(h_1 - h_3)}$$

Next find v_m and v'_3. Then, from the equation of continuity,

$$A_m = wv_m/V_m \quad \text{and} \quad A'_3 = wv'_3/V'_3$$

The following example illustrates the method.

Example. Required the throat and end sections of a nozzle to deliver 0.7 lb of steam per sec. The initial pressure is 160 lb, the back pressure 15 lb, and the steam is initially superheated 100 F; $y = 0.15$.

The critical pressure is $160 \times 0.55 = 88$ lb. On the Mollier chart (Fig. 35), the point A representing the initial state is located, and line of constant entropy (a frictionless adiabatic) is drawn from A. This cuts the curves $p = 88$ and $p = 15$ in the points B and C, respectively. The three values of h are found to be $h_1 = 1253$, $h_m = 1199$, $h_3 = 1067$. Of the available drop in enthalpy, $h_1 - h_3 = 185.5$ Btu, 15 per cent or 27.9 Btu is lost through friction. Hence, $CD = 27.9$ is laid off and D is projected horizontally to point C' on the curve $p = 15$. Then C' represents the final state of the steam, and the quality is found to be $x = 0.943$. The specific volume in the state C' is $26.29 \times 0.943 = 24.8$ cu ft. Likewise, the specific volume for the state B is found to be 5.29 cu ft.

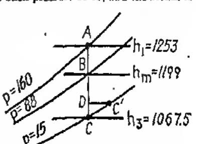

FIG. 35.

For the velocities at throat and end sections,

$$V_m = 223.7\sqrt{1253 - 1199} = 1643 \text{ fps}$$
$$V_3 = 223.7\sqrt{185.5 - 27.9} = 2813 \text{ fps}$$
$$A_m = (0.7 \times 5.29)/1643 = 0.00225 \text{ sq ft} = 0.324 \text{ sq in.}$$
$$A_3 = (0.7 \times 24.8)/2813 = 0.00617 \text{ sq ft} = 0.89 \text{ sq in.}$$

The diameters are $d_m = 0.643$ in. and $d_3 = 1.064$ in.

Divergence of Nozzles. The diagram (Fig. 36) gives, for various ratios of expansion, the required "divergence" of the nozzle, *i.e.*, the ratio of the area of any section to the throat area. Thus in the case of saturated steam, if the final pressure is $\frac{1}{15}$ of the initial pressure the ratio of the areas is 3.25. The curves apply to frictionless flow; the effect of friction is to increase the divergence.

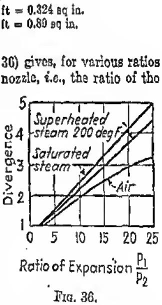

FIG. 36.

Theory of Supersaturation. Certain discrepancies between the discharge of saturated steam through an orifice as calculated from the preceding theory and the discharge actually observed are explained by a hypothesis first advanced by Martin, *viz.*, that steam when expanded rapidly, as in turbine nozzles, becomes supersaturated; in other words, the condensation required by the ordinary theory of adiabatic expansion does not occur on account of the rapidity of the expansion (see Goodenough, *Power*, Sept. 27, Oct. 4, 1927).

The following example from the article cited illustrates the effect of supersaturation on the flow of steam. Let the initial condition of the steam be $p_1 = 40$ lb per sq in. abs, $t_1 = 283.2$ F (16 deg superheat), $v_1 = 10.76$ cu ft per lb, $s_1 = 1.6877$. The steam expands adiabatically in a nozzle to a pressure of 20 lb per sq in. Two calculations are made. (1) It is assumed that equilibrium conditions are maintained and that after the saturation state is reached the expansion is accompanied by condensation. (2) It is assumed that there is no condensation and that the steam follows the gas law

lent of the work done on the gas during the contraction. For example, in the burning of CO according to the equation $CO + \frac{1}{2}O_2 = CO_2$, there is a contraction of $\frac{1}{2}$ volume. Taking 62 F as the temperature, the volume of 1 lb CO at atmospheric pressure is 13.6 cu ft; hence the equivalent of the work done at atmospheric pressure is $\frac{1}{2} \times 13.6 \times 2116/778 = 18.5$ Btu, which is about 0.4 percent of the heat value of CO. Since the difference between H_p and H_v is small in most fuels, it is usually neglected.

It is also to be noted that heat values vary with the initial temperature (which is also the final temperature), but the variation is usually negligible.

Heat Value per Unit Volume. Since the consumption of a fuel gas is more easily measured by volume than by weight, it is convenient to express heat values in terms of volumes. For this purpose, a standard temperature and pressure must be assumed. It is customary to take atmospheric pressure (14.70 lb per sq in.) as standard, but there is diversity of practice in the matter of a standard temperature. The temperature of 68 F (20 C) is generally accepted in metric countries and has been recommended by the American delegates to the meeting of the International Committee of Weights and Measures and also by the A.S.M.E. Power Test Codes Committee. The American Gas Assoc. uses 60 F as the standard temperature of reference. Conversion of density and heat values from 68 to 60 F of dry (saturated) gas is obtained by multiplying by the factor 1.0154 (1.0212). Conversion of specific volumes of dry (saturated) gas is obtained by multiplying by the factor 0.9848 (0.9792).

If the gas is at some other pressure and temperature, say p_1 lb per sq in. abs and T_1 deg R, the heat value per cubic foot is found by multiplying the heat value per cubic foot under standard conditions by $35.9p_1/T_1$.

Table 32. Heats of Combustion

Fuel	Chemical symbol	High heat value, Btu		Low heat value, Btu	
		Per lb	Per cu ft[a]	Per lb	Per cu ft[a]
Carbon to CO_2	C	14,520			
Carbon to CO	C	4,340			
CO to CO_2	CO	4,345	315.8		
Sulphur	S	3,982			
Hydrogen	H_2	61,045	319.5	51,608	270.1
Methane	CH_4	23,910	995.4	21,529	896.2
Ethane	C_2H_6	22,330	1,739	20,425	1,591
Propane	C_3H_8	21,670	2,475	19,940	2,278
Butane	C_4H_{10}	21,320	3,211	19,670	2,960
Pentane	C_5H_{12}	21,100	3,944	19,514	3,647
Hexane	C_6H_{14}	20,950	4,676	19,400	4,330
Octane	C_8H_{18}	20,750	6,141	19,245	5,694
Decane	$C_{10}H_{22}$	20,700	7,630	19,350	7,132
Ethylene	C_2H_4	21,660	1,577	20,300	1,478
Propylene	C_3H_6	21,330	2,325	19,970	2,177
Acetylene	C_2H_2	21,570	1,457	20,840	1,407
Benzene	C_6H_6	18,160	3,677	17,190	3,481
Toluene	C_7H_8	18,300	4,370	17,460	4,169
Methyl alcohol	CH_4O	10,270	853.1	9,078	754.1
Ethyl alcohol	C_2H_6O	13,120	1,573	11,930	1,424
Naphthalene	$C_{10}H_8$	17,300	5,749	16,700	5,549

[a] Measured as a gas at 68 F and 14.70 lb per sq in. abs. Multiply by 1.0154 for 60 F and 14.70 lb.

uniform diameter, dF is approximately equal to $2f\frac{V^2dL}{gD}$. It is usual to express friction due to fittings, etc., in terms of additional length of pipe, adding this to the actual pipe length to get the equivalent pipe length.

Integration of the fundamental equation leads to two sets of formulas.

1. For pressure drops, small relative to the initial pressure, the specific volume v and the velocity V may be assumed constant. Then approximately

$$p_1 - p_2 = 2fV^2L/vgD$$

Expressing pressure in pounds per square inch, p', the diameter in inches,

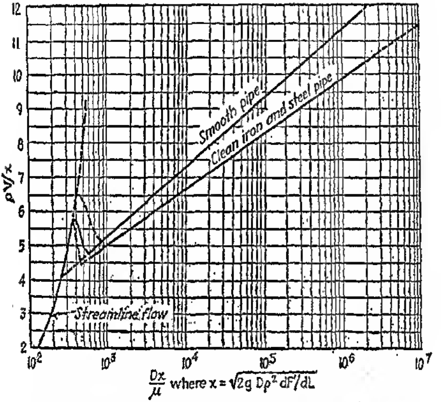

FIG. 37.—Chart for Estimating Rate of Flow from the Pressure Gradient.

and V as a function of wv/D^2, this equation becomes

$$p'_1 - p'_2 = 174.2fw^2vL/d^5$$

2. For considerable pressure drops, when dealing with approximately isothermal flow of gases and vapors to which the gas laws are applicable, the fundamental equation may be integrated to give

$$p_1^2 - p_2^2 = \frac{2w^2RT}{gA^2}\log_e\frac{v_2}{v_1} + \frac{4fRTw^2L}{gA^2D}$$

Coefficients of Friction. The coefficient of friction f is not a constant but is a function of the dimensionless expression $\mu/\rho Vd$ or $\mu v/Vd$, which is the reciprocal of the Reynolds number. McAdams and Sherwood (*Mech. Eng.*, Oct., 1926) formulate the expression

$$f = 0.0054 + 0.375(\mu v/Vd).$$

This formula is applicable to water and other fluids. For high-pressure steam, the second term in the expression is small and f is approximately equal

Low and High Heat Values. Any fuel containing hydrogen yields water as one product of combustion. At atmospheric pressure, the partial pressure of the water vapor in the resulting combustion gas mixture will usually be sufficiently high to cause water to condense out if the temperature is allowed to fall below 120–140 F. This causes liberation of the heat of vaporization of any water condensed. The low heat value is evaluated assuming no water vapor condensed, whereas the high heat value is calculated assuming all water vapor condensed.

To facilitate calculations of the temperature attained by combustion, it is desirable to make use of the low heat value. The necessity of taking into account the heat of vaporization of the water vapor and the difference between the specific heats of liquid water and of water vapor is thus avoided. The high heat of combustion exceeds the low heat of combustion by the difference between the heat actually given up on cooling the products to the initial temperature and that which would have been given up if the products had remained in the gaseous state. A bomb calorimeter (constant volume) gives practically correct values of the high heat value; a gas calorimeter (constant pressure) gives values which, for the usual fuels, may be incorrect by a fraction of 1 percent. The quantity to be subtracted from the high heat value to obtain the low heat value will vary with the composition of the fuel; an approximate value is 1050 m, where m is the number of pounds of H_2O formed per pound of fuel burned.

In Germany, the low heat value of the fuel is used in calculating efficiencies of internal-combustion engines. In the United States, the high value is specified by the A.S.M.E. Power Test Codes.

Heat of Formation. The change in enthalpy resulting when a compound is formed from its elements isothermally and at constant pressure is called the heat of formation. It is equal to the difference between the heats of combustion of the constituents forming the compound and the heat of combustion of the compound itself. The following values for heats of formation are in Btu per lb of the compound. The elements before the change and the compounds formed are assumed in their ordinary stable states at 65 F and 1 atm. A plus sign indicates heat evolved on forming the compound, a minus sign heat absorbed from the surroundings.

Fuels. Methane, CH_4, (gas) 2048; ethane, C_2H_6, (gas) 1258; propane, C_3H_8, (vapor) 1440; acetylene, C_2H_2, (gas) −3730; ethylene, C_2H_4, (gas) −707.3; benzene, C_6H_6, (vapor) −288; toluene, C_7H_8, (vapor) −68; methyl alcohol, CH_3OH, (liquid) 3234; ethyl alcohol, C_2H_5OH, (liquid) 2625.

Inorganic Compounds. Al_2O_3, 9234; CaO, 7585; $CaCO_3$, 5211; FeO, 1608; Fe_2O_3, 2243; Fe_3O_4, 2071; FeS_2, 532.5; HCl (gas), 1088; HNO_3 (liquid), 1191; H_2O (liquid), 6837; H_2S, 280.4; H_2SO_4 (liquid), 3365; K_2O, 1646; MgO, 6531; MnO, 2441; NO, −1296; N_2O, −803.7; Na_2O, 2884; NH_3, 1165; NH_4Cl, 2518; NiO, 1407; P_2O_5 (solid), 4572; PbO, 424.9; PbO_2, 488.8; SO_2, 1993; SnO, 907.2; ZnO, 1845.

Internal Energy and Enthalpy of Gases. Table 34 gives the internal energy of various common gases in Btu per lb mol measured above 520 R (60 F). The corresponding values of the enthalpy are obtained by adding the value of Apv from the last column.

Temperature Attained by Combustion. Excluding the effect of dissociation, the temperature attained at the end of combustion may be calculated by a simple energy balance. The heat of combustion less the heat

Throttling

Throttling or Wiredrawing. When a fluid flows from a region of higher pressure into a region of lower pressure through a valve or constricted passage, it is said to be throttled or wiredrawn. Examples are seen in the passage of steam through pressure-reducing valves, in the flow through ports and passages in the steam engine, and in the expansion valve of the refrigerating machine.

The general equation applicable to throttling processes is

$$(V_2^2 - V_1^2)/2g = (h_1 - h_2)J$$

The velocities V_2 and V_1 are practically equal, and it follows that $h_1 = h_2$; *i.e.*, in a throttling process there is no change in enthalpy.

For a mixture of liquid and vapor, $h = h_f + xh_{fg}$; hence the equation of throttling is $h_{f1} + x_1h_{fg1} = h_{f2} + x_2h_{fg2}$. In the case of a perfect gas, $h = c_pT + h_0$; hence the equation of throttling is $c_pT_1 + h_0 = c_pT_2 + h_0$, or $T_1 = T_2$.

Joule-Thomson Effect. The investigations of Joule and Lord Kelvin showed that a gas drops in temperature when throttled. This is not universally true. For some gases, notably hydrogen, the temperature rises for throttling processes over ordinary ranges of temperature and pressure. Whether there is a rise or fall in temperature depends on the particular range of pressure and temperature over which the change occurs. For every gas, there is one temperature at which no temperature change occurs during a Joule-Thomson expansion; this is called the **inversion temperature.** Below this temperature, a gas cools on throttling; above this temperature, its temperature rises. The ratio of the observed drop in temperature to the drop in pressure, *i.e.*, dT/dp, is the **Joule-Thomson coefficient.**

The variations of the Joule-Thomson coefficient, for air, with both temperature and pressure, can be determined from the constant enthalpy curves of Fig. 17. Values of the coefficient for steam vary from 0.465 at 300 deg to 0.165 at 530 F, the unit being deg per lb per sq in.

The cooling effect produced by throttling has been applied to the liquefaction of gases (see p. 352).

Loss Due to Throttling. A throttling process in a cycle of operations always introduces a loss of efficiency. If T_0 is the temperature corresponding to the back pressure, the loss of available energy is the product of T_0 and the increase of entropy during the throttling process. The following example illustrates the calculation in the case of ammonia passing through the expansion valve of a refrigerating machine.

Example. The liquid ammonia at a temperature of 70 F passes through the valve into the brine coil in which the temperature is 20 deg and the pressure is 48.21 lb per sq in. The initial enthalpy of the liquid ammonia (see Table 25) is $h_{f1} = 120.5$, and therefore the final enthalpy is $h_{f2} + x_2h_{fg2} = 64.7 + 553.1x_2 = 120.5$, whence $x_2 = 0.101$. From the table, the initial entropy is $s_{f1} = 0.254$. The final entropy is $s_{f2} + (x_2h_{fg2}/T_2) = 0.144 + 0.101 \times 1.153 = 0.260$. $T_0 = 20 + 460 = 480$; hence the loss of refrigerating effect is $480 \times (0.260 - 0.254) = 2.9$ Btu.

COMBUSTION

Fuels. For special properties of various fuels, see pp. 1006 and 1014. In general, fuels may be classed under three heads: (1) gaseous fuels, (2) liquid fuels, (3) solid fuels.

The combustible elements that characterize fuels are carbon, hydrogen, and, in some cases, sulphur. The complete combustion of carbon gives,

lost by conduction and radiation during the process is equal to the increase in internal energy of the products mixture if the combustion is at constant volume; or, if the combustion is at constant pressure, the difference is equal *to the increase in enthalpy of the products mixture.*

As an **example**, the temperature of combustion of a fuel gas having the composition $H_2 = 0.50$, $CO = 0.40$, $CO_2 = 0.04$ is calculated. The gas is burned with 15 percent excess air at constant volume, and the initial temperature in 62 F, *i.e.* $T = 522$.

The volume composition of the initial mixture of fuel gas and air and the mixture of products are, respectively:

Initial: H_2, 0.50; CO, 0.46; CO_2, 0.04; O_2, 0.552; N_2, 2.098

Products: H_2O, 0.50; CO_2, 0.50; O_2, 0.072; N_2, 2.098

Since a volume composition is also a mol composition, the products mixture may be regarded as made up of 0.5 mol each of H_2O and CO_2, 0.072 mols of O_2, and 2.098 mols of N_2. If values are taken from Table 32, the heat generated by combustion of the fuel mixture in $0.50 \times 2 \times 51{,}608 + 0.46 \times 28 \times 4345 = 107{,}584$ Btu. The internal energy u of the products mixture at $T = 522$ is now calculated. For 0.5 mol H_2O + 0.5 mol CO_2 + 0.072 mol O_2 + 2.098 mol N_2 this is $3.05 + 3.48 + 0.36 + 10.17 = 17.06$ Btu.

The *energy u_2 of the mixture is next calculated for various assumed temperatures*, the proper values being taken from Table 34.

T_2 assumed	4700	4800	4900	5000	5200
Energy 0.5 mol H_2O	18,308	18,851	10,391	19,943	20,492
Energy 0.5 mol CO_2	23,742	24,358	25,035	25,682	26,331
Energy 0.072 mol O_2	1,976	2,026	2,080	2,135	2,185
Energy 2.098 mol N_2	53,500	55,017	56,446	57,882	59,321
$u_2 =$	97,526	100,282	102,952	105,642	108,329
$u_1 =$	17	17	17	17	17
	97,509	100,265	102,935	105,625	108,312

If the heat of combustion, 107,584 Btu, *is entirely used in the increase of energy*, the temperature attained lies somewhere between 5000 and 5200; by interpolation, the value 5140 deg is obtained.

Loss of heat during combustion may readily be taken into account; then if 10 percent *of the heat of combustion is lost, the amount available for increasing the energy of the* products is $107{,}584 \times 0.90 = 96{,}827$ Btu, and this increase gives $T_2 = 4670$ deg. If the fuel is burned at constant pressure, H_p is used instead of H_v and values of h are determined from Table 34 instead of values of u.

Effect of Dissociation. The maximum temperature that can be obtained by the combustion of any fuel is limited by the dissociation of the products formed. Thus CO_2 dissociates into CO and $\frac{1}{2}O_2$, whereas H_2O goes to $H_2 + \frac{1}{2}O_2$. The amount of such dissociation depends upon the temperature and also upon the pressure; the higher the pressure, the less the dissociation. The percentage dissociation, according to Tizard and Pye (*Automobile Eng.*, Feb. 1921) is given in Table 35.

Table 35. Dissociation of H_2O and CO_2
(Dissociation, percent)

Temperature, deg F	Pressure, atm							
	0.1	1.0	10	100	0.1	1.0	10	100
	H_2O				CO_2			
2730	0.043	0.02	0.009	0.004	0.104	0.048	0.0224	0.01
3630	1.25	0.58	0.27	0.125	4.35	2.05	0.96	0.445
4530	8.84	4.21	1.98	0.927	33.5	17.6	8.63	4.09
5430	28.4	14.4	7.04	3.33	77.1	54.8	32.2	16.9

	V	Coefficients in reaction equations O_2	CO_2	H_2O	Coefficients multiplied by V O_2	CO_2	H_2O
H_2	0.08	0.5	0	1	0.04	0	0.08
CO	0.22	0.5	1	0	0.11	0.22	0
CH_4	0.024	2	1	2	0.048	0.024	0.048
CO_2	0.066	0	1	0	0	0.066	0
N_2	0.61	0	0	0	0	0	0
	1.0				0.198	0.31	0.128

For 1 cu ft of the producer gas, 0.198 cu ft of O_2 is required for complete combustion. The minimum volume of air required is $0.198/0.21 = 0.943$ cu ft and with 20 percent excess the air supplied is $0.943 \times 1.2 = 1.132$ cu ft. Of this, 0.238 cu ft is oxygen and 0.894 cu ft is N_2. Consequently, for 1 cu ft of the fuel gas, the exhaust gas contains

CO_2	0.31 cu ft	or	CO_2	15.7 percent
H_2O	0.128 cu ft		H_2O	6.5 percent
N_2 ..... $0.61 + 0.894 =$	1.504 cu ft		N_2	75.8 percent
O_2 (excess) ... $0.238 - 0.198 =$	0.040 cu ft		O_2	2.0 percent
	1.982 cu ft			100.0 percent

Volume Contraction. As a result of chemical action, there is often a change of volume; for example, in the reaction $2H_2 + O_2 = 2H_2O$, three volumes (two of H_2 and one of O_2) contract to two volumes of water vapor. In the example just given, the volume of producer gas and air supplied is 1 cu ft gas + 1.132 cu ft air = 2.132 cu ft, and the corresponding volume of the exhaust gas is 1.982 cu ft, showing a contraction of about 7 percent. For a hydrocarbon having the composition C_mH_n, the relative volume contraction is $[1 - (n/4)]$; thus for CH_4 and C_2H_4 there is no change of volume, for C_2H_2 the contraction is ½ volume, and for C_2H_6 there is an increase of ½ in volume.

The change of volume accompanying a chemical reaction, such as a combustion, causes a corresponding change in the gas constant R. Let R' denote the constant for the mixture of gas and air (1 lb of gas and xa lb of air) before combustion, and R'' the constant of the mixture of resulting products of combustion. Then, if y is the resulting contraction of volume, $R''/R' = (1 + xa - y)/(1 + xa)$.

Heat of Combustion. Usually, a chemical change is accompanied by the generation or absorption of heat. The union of a combustible with oxygen produces heat, and the heat thus generated when 1 lb of combustible is completely burned is called the **heat of combustion** or the **heat value** of the combustible. Heat values are determined experimentally by calorimeters in which the products of combustion are cooled to the initial temperature and the heat absorbed by the cooling medium is measured. This is called the high heat value.

An accurate definition of the heat value requires specification of the conditions under which the combustion proceeds. Two heat values may thus be distinguished:

1. The **heat value at constant volume** (H_v) is the quantity of heat rejected, from a calorimeter, to external surroundings when the temperature and volume of the combustion products are brought to the temperature and volume, respectively, of the gaseous mixture before burning. Numerically, this is equal to the change in internal energy.

2. The **heat value at constant pressure** (H_p) is the quantity of heat rejected, from a calorimeter, when the temperature and pressure of the products are brought back to the temperature and pressure, respectively, of the gaseous mixture before burning. This is equal to the change in enthalpy.

If there is no change of volume due to the combustion, the heat values H_p and H_v are the same. When there is a contraction of volume, H_p exceeds H_v by the heat equiva-

pheric pressure. This was compressed to $\frac{1}{6}$ of its volume and exploded. It was assumed that no heat was lost during explosion. With no dissociation, the maximum temperature reached is 5473 F and the maximum pressure 658 lb per sq in. With dissociation, the maximum temperature is 4811 F and the maximum pressure 600.7 lb per sq in. Similar results are found for other liquid fuels, as alcohol, kerosene, etc.

As the temperature falls after reaching the maximum, the uncombined CO and H_2 burn with the oxygen present, and when the temperature has reached about 3000 F the combustion is practically complete. Thus in the internal-combustion engine dissociation has the effect of reducing the explosion temperature and pressure and afterward of raising the expansion curve. The effect on the efficiency is not large. For an engine using benzene according to the conditions just noted, the ideal efficiency with no heat loss and without dissociation was found by Tizard and Pye to be 35.9 percent; with dissociation and subsequent recombination, it was found to be 33.8 percent.

Combustion of Solid Fuels

For properties of coals, heat values, etc., see p. 1014.

Air Required for Combustion. Let c, h, and o, denote, respectively, the parts by weight of carbon, hydrogen, and oxygen in 1 lb of the fuel. Then the **minimum weight of oxygen** required for complete combustion is $2.67c + 8h - o$ lb, and the **minimum weight of air** required is $a = (2.67c + 8h - o)/0.23 = 11.6[c + 3(h - o/8)]$ lb.

With air at 62 F and at atmospheric pressure, the minimum volume of air required is $v_m = 147[c + 3(h - o/8)]$ cu ft. In practice, an excess of air over that required for combustion is admitted to the furnace. The actual weight admitted per pound of fuel may be denoted by xa. Then x = weight admitted ÷ minimum weight.

Combustion Products. If v_m is the minimum volume of air required for complete combustion and xv_m the actual volume supplied, then the products will contain per pound of fuel, $O_2 = 0.21v_m(x - 1)$ cu ft, $N_2 = 0.79\,xv_m$ cu ft.

From the reaction equation $C + O_2 = CO_2$, the volume of CO_2 formed is equal to the volume of oxygen required for the carbon constituent alone; hence volume of $CO_2 = 0.21v_mc/[c + 3(h - 0.125o)]$.

Of the *dry* gaseous products (i.e., without water), the CO_2 content by volume is therefore given by the expression

$$CO_2 = 0.21c/[xc + (x - 0.21)3(h - 0.125o)]$$

The combined CO_2 and O_2 content is

$$CO_2 + O_2 = 0.21\{1 - 0.79/[x + cx/3(h - 0.125o) - 0.21]\}$$

If the fuel is all carbon, the combined CO_2 and O_2 is by volume 21 percent of the gaseous products. The more hydrogen contained in the fuel, the smaller is the $CO_2 + O_2$ content. The CO_2 content depends in the first instance on the excess of air. Thus, for pure carbon, it is $CO_2 = 0.21/x$.

The excess of air may be calculated from the composition of the gases and that of the fuel. Thus

$$x = 0.21\left[\frac{c}{[CO_2]} + 3(h - 0.125o)\right] \Big/ [c + 3(h - 0.125o)],$$

in which $[CO_2]$ denotes the percent by volume of the CO_2 in the dry gas.

Table 33. Products of Combustion
(From Marks, "The Airplane Engine")

Fuel	Chemical formula	Molecular weight $O_2 = 32$	Specific weight, lb per cu ft at 68 F and 14.70 lb per sq in.	Volume of air necessary for combustion of unit volume of fuel at same temperature and pressure	Products of combustion of 1 cu ft of fuel in theoretical amount of air, cu ft			Weight of air necessary for combustion of unit weight of fuel	Products of combustion of 1 lb of fuel in theoretical amount of air, lb		
					CO_2	H_2O	N_2		CO_2	H_2O	N_2
Oxygen	O_2	32	0.0831

Heat Value per Unit Volume of Mixture. Let a denote the volume of air required for the combustion of 1 cu ft of fuel gas and xa the value of air actually admitted, $x - 1$ being therefore the excess. Then the volume of the mixture of fuel gas and air is $1 + xa$, and the quotient $H/(1 + xa)$ may be called the heat value per cubic foot of mixture. This magnitude is useful in comparing the relative volumes of mixture required with different fuel gases. Thus a lean gas, as blast-furnace gas or producer gas, has a low heat value H, but the value of a is correspondingly low. On the other hand, a rich gas, like natural gas, has a high heat value but requires a large volume of air for combustion.

The ratio of air supplied per pound of combustible to that theoretically required is $N/[N - 3.782(O - \frac{1}{2}CO)]$, on the assumption that all the nitrogen in the flue gas comes from the air supplied. Figure 39 gives the value of this ratio for varying flue-gas analyses where there is no CO present.

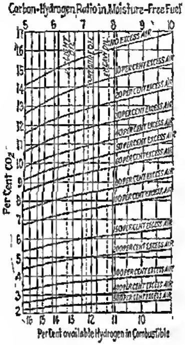

FIG. 40.—Relation of CO_2 to Excess Air for Oil Fuels.

For petroleum fuels with hydrogen content from 9 to 16 percent, the excess air can be determined from the CO_2 content of the flue gases (with no CO present) by the use of Fig. 40. The curves are based on the assumption of 0.4 percent sulphur in the oil.

Table 34. Internal Energy of Gases

(Btu per lb mol above 520 R)

(From L. C. Lichty, "Internal Combustion Engines," 1939, p. 582, derived from data given by Hershey, Eberhardt and Hottel, *Trans. S.A.E.*, 31, 1936, p. 409)

precise work, it requires frequent calibration. (3) The wet- and dry-bulb psychrometer is most widely used. For precise work, radiation to the wet bulb must be considered. The velocity of atmospheric movement past the wet bulb affects the temperature attained; at about 1,200 fpm, the maximum wet-bulb depression is reached. This velocity is set up by a fan blowing over the wet bulb or by swinging the wet bulb vigorously. An unventilated wet bulb is unreliable. At the wet-bulb temperature, the rate of evaporation and the diffusion of water vapor (dependent upon the excess of p_w over p_v) are balanced by the rate of heat transfer from the surrounding atmosphere to the wet bulb (dependent upon the wet-bulb depression). A constant is determined by calibration.

The electric hygrometer is a device whose electrical resistance or capacity varies with the relative humidity of the surrounding air. For details see Dunmore, "An Improved Electric Hygrometer," *Jour. Research, B. of S.*, *23, p. 701, Dec., 1939; also Research Paper 1265.*

Table 1 gives the pressure-temperature relations for saturated water vapor over water or ice.

Table 1. Vapor Pressure of Water in Inches of Hg at 32 F
(Ice below 32 F)
(From Keenan and Keyes, "Thermodynamic Properties of Steam")

The following equations give various quantities in terms of vapor pressure and observed quantities. Equation (1) (Apjohn, 1835) is sufficiently accurate for most purposes, with a modified value of the constant.

The suggested degree of accuracy for each equation corresponds to temperature readings to the nearest degree F. An additional significant digit demands temperature readings accurate to at least 0.1 F (Berry, *loc. cit.*).

Vapor pressure: $$p_v = p_w - B(t_d - t_w)/2700 \qquad (1)$$

Relative humidity: $$r = p_v/p_d \qquad (2)$$

Molal humidity: $$m = p_v/(B - p_v) \quad \text{or} \quad p_v = mB/(1 + m) \qquad (3)$$

Specific humidity: $$s = m/1.61 = p_v/1.61(B - p_v) \qquad (4)$$

Air density: $$\rho_a = (B - p_v)/RT_d \qquad (5)$$

(R = 0.3704 for pressures in lb per sq in. = 0.7541 in in. of Hg)

Vapor density: $$\rho_v = \rho_a s \qquad (6)$$

Mixture density: $$\rho_m = \rho_a + \rho_v = \rho_a(1 + s) = (B - 0.38p_v)/RT_d \qquad (7)$$

By means of the equilibrium equations for the H_2 and CO reactions, it is possible to calculate the maximum temperature when equilibrium is attained, and also the amount of dissociation of H_2O and CO_2.

To show the extent of the dissociation, Table 36 (calculated by G. T. Felbeck), is given. The values are based on the following assumptions:

1. The mixture of fuel and air has an initial pressure of 14.7 lb per sq in. and an initial temperature of 60 F.
2. The combustion is at constant volume as in the ideal Otto cycle.
3. The loss of heat is taken as 10 percent of the heat of combustion.

Table 36. Percentage Dissociation and Explosion Temperatures of Various Fuel Mixtures

(x = dissociation of CO_2, percent; y = dissociation of H_2O, percent; T = temperature deg F abs)

Fuel		Percent excess air 0	10	20	30	40

	x	13.1	5.9	2.9	1.5	0.6
	y	1.9	0.9	0.4	0	0
Producer gas	T	3810.0	3720.0	3620.0	3510.0	3410.0
	x	2.9	1.5	0.4	0	0
	y	0.5	0.2	0.1	0	0
Blast furnace gas	T	3560.0	3500.0	3420.0	3340.0	3250.0
	x	1.4	0.4	0	0	0
	y	0.2	0	0	0	0

Inspection of Table 36 shows (1) that the dissociation of H_2O is negligible for temperatures below 4700 deg abs; (2) that the dissociation of CO_2 may reach an appreciable magnitude if the absolute temperature exceeds 4300 F, (3) that an excess of air by reducing the temperature reduces the dissociation; (4) that dissociation is less for the lean gases than for the rich gases.

The maximum temperature attainable by the combustion of hydrogen with oxygen at atmospheric pressure is about 5270 F. In the oxyacetylene flame, the temperature may be as high as 6020 F.

In the case of **explosion in the internal-combustion engine**, the figures in the table will be somewhat changed. The effect of compression is to increase both the initial temperature and the initial pressure. The resulting increase in the explosion temperature will tend to increase the dissociation, the increase of pressure will tend to reduce it. The net effect will be a small reduction.

Combustion of Liquid Fuels. For properties of fuel oils, heat values, etc., see page 1006. Calculations for the burning of liquid fuels are fundamentally the same as for gaseous fuels. Liquid fuels are almost always gasified before or during actual combustion.

Tizard and Pye (*Automobile Eng.*, Feb., 1921) give the following result on a theoretically correct mixture of benzene vapor and air at 212 F and atmos-

$$\Sigma = h_m - s \times (t_w - 32) = 0.240t_d + s \times (h_v - t_w + 32) \text{ Btu per lb air} \quad (10)$$

An advantage of the sigma function is that it is determined by the barometric pressure and the wet-bulb temperature; its value is independent of the dry-bulb temperature. It equals the enthalpy of dry air at the given wet-bulb temperature; at zero relative humidity, the sigma function and the enthalpy are identical. Values are given in Table 2. The sigma function has a shifting datum depending upon the wet-bulb temperature; in any change of state during which the wet-bulb temperature changes, correction must be made for this.

Examples. 1. To Find p_v from Psychrometer Data. $B = 24$ in. Hg; $t_d = 76$ F; $t_w = 62$ F. From Table 1, $p_w = 0.56$ in. Hg. From Eq. (1), $p_v = 0.56 - [24(76 - 62)/2700] = 0.44$ in. Hg.

2. To Find p_v from Temperature and Relative Humidity. $t_d = 72$ F, $r = 0.73$. From Table 1, $p_d = 0.79$ in. Hg. From Eq. (2), $p_v = r \times p_d = 0.73 \times 0.79 = 0.58$ in. Hg.

3. To Find Composition, Density, Etc.

$$B = 28 \text{ in. Hg}; \qquad t_d = 82 \text{ F}; \qquad t_w = 70 \text{ F}; \qquad p_v = 0.62 \text{ in. Hg}.$$

Relative humidity: from Table 1, $p_d = 1.10$ in. Hg; from Eq. (2), $r = 0.62/1.10 = 0.56$ or 56 percent.

Molal humidity: from Eq. (3), $m = 0.62/(28 - 0.62) = 0.0226$ mols vapor per mol air.

Specific humidity: from Eq. (4), $s = 0.62/1.61 \times (28 - 0.62) = 0.0141$ lb vapor per lb air (7,000 grains = 1 lb avdp.) = 99 grains vapor per lb air.

Air density: from Eq. (5), $\rho_a = (28 - 0.62)/0.754 \times 542 = 0.0670$ lb air per cu ft.

Mixture density: from Eq. (7), $\rho_m = (28 - 0.38 \times 0.62)/0.754 \times 542 = 0.0680$ lb air + vapor per cu ft.

Enthalpy: from Eq. (8), $h_v = 1062 + 0.44 \times 82 = 1098$ Btu per lb vapor; from Eq. (9), $h_m = 0.240 \times 82 + 0.0141 \times 1098 = 35.2$ Btu per lb air.

Sigma-function: from Eq. (10) $\Sigma = 0.240 \times 82 + 0.0141 \times (1098 - 70 + 32) = 34.8$ Btu per lb air.

Psychrometric Charts. For occasional use, algebraic equations are less confusing and more reliable; for frequent use, a psychrometric chart may be preferable. A disadvantage of charts is that each applies for only one value of barometric pressure, usually 760 mm or 30 in. of mercury. *Correction to other barometric readings is not simple.* The equations have the advantage that the actual barometric pressure is taken into account. The equations are often more convenient for equal accuracy or more accurate for equal convenience.

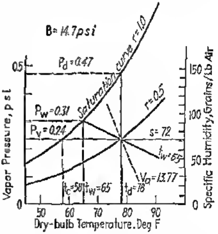

FIG. 1.—Skeleton Humidity Chart.

Psychrometric charts are usually plotted, as indicated by Fig. 1, with dry-bulb temperature as abscissa and specific humidity as ordinate. Since the specific humidity is determined by the vapor pressure and the barometric pressure (which is constant for a given chart), and is nearly proportional to the vapor pressure, a second ordinate scale, departing slightly from uniform

The temperature of combustion is calculated by the same method as for gaseous fuels.

Loss Due to Incomplete Combustion. The loss due to incomplete combustion of the carbon in the fuel, in Btu per lb of fuel, is

$$L = 10{,}180C \times CO/(CO + CO_2)$$

where 10,180 = difference in heat evolved in burning 1 lb of carbon to CO_2 and to CO; CO and CO_2 = percentages by volume of carbon monoxide and carbon dioxide as found by analysis; and C = fraction by weight of carbon in the fuel which is actually burned and passes up the stack, either as CO or CO_2. The presence of 1 percent of CO in the flue gases will represent a decrease in the boiler efficiency of 4.5 percent. An additional loss is caused by passage through the grate to the ashpit of any unburned or partly burned fuel.

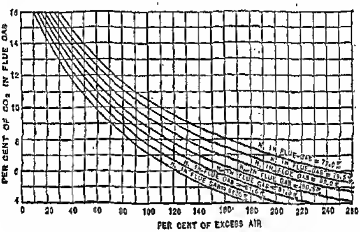

FIG. 39.—Ratio of Air Supplied per Pound of Combustible to That Theoretically Required.

It is generally assumed that high CO_2 readings are indicative of good combustion and, hence, of high efficiencies. Such readings are not satisfactory when considered apart from the CO determination. The best percentage of CO_2 to maintain varies with different fuels and is lower for those with a high hydrogen content than for fuel mainly composed of carbon.

Hydrogen in a fuel increases the nitrogen content of the flue gases. This is due to the fact that the water vapor formed by the combustion of hydrogen will condense at the temperature at which the analysis is made, while the nitrogen which accompanied the oxygen maintains its gaseous form and passes in that form into the sampling apparatus. For this reason, where highly volatile coals containing considerable hydrogen are burned, the flue gas contains an apparently increased amount of nitrogen. The effect is even more pronounced when burning gaseous or liquid hydrocarbon fuels.

The weight of flue gases per pound of fuel, including moisture formed by the hydrogen component, is approximately $= 3.02\,[N/(CO_2 + CO)]C + (1 - A)$, where A = percent of ash as found in test. The weight of dry flue gases per pound of fuel may be approximated from the formula: $W_2 = C[11CO_2 + 8O + 7(CO + N)]/3(CO_2 + CO)$. In these formulas, the weight of gas is per pound of dry or moist fuel as the percentage of C is referred to a dry or moist basis.

The ratio of air supplied per pound of fuel to the air theoretically required is $W_1/W = 3.02C\left(\dfrac{N}{CO_2 + CO}\right)\Big/34.56\left(\dfrac{C}{3} + H - \dfrac{O}{8}\right)$.

graduations, will give the vapor pressure. The saturation curve ($r = 1.0$) gives the specific humidity and vapor pressure for a mixture of air and saturated vapor. Similar curves below it give results for various values of relative humidity. Inclined lines of one set carry fixed values of the wet-bulb temperature, and those of another set carry fixed values of v_a, cubic feet per pound of air, the reciprocal of the air density given by Eq. (5).

Any two values will locate the point representing the state of the atmosphere, and the desired values can be read directly.

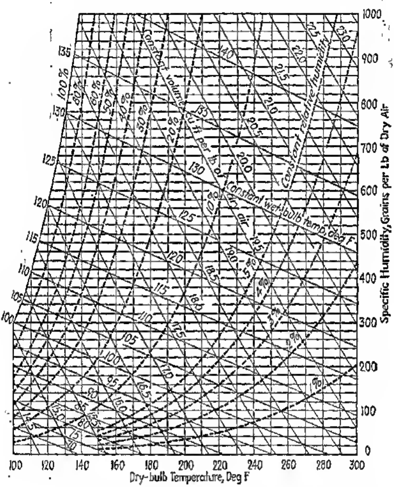

FIG. 3.—Humidity Chart for Medium Temperatures. (From Ellenwood and Mackey, "Vapor Charts," Wiley.)

Figures 2 and 3 are psychrometric charts from Ellenwood and Mackey, ("Vapor Charts," Wiley) covering a dry-bulb temperature range from 32 to 300 F. They are accurate only for a barometric pressure of 29.92 in. Hg.

Air-conditioning processes alter the temperature and specific humidity of the atmosphere. The weight of air remains constant and consequently computations are best based upon 1 lb of air.

Liquid water may enter or leave the apparatus. Its weight W_f lb per lb of air is often merely the difference between the specific humidities of the

MIXTURES OF GASES AND VAPORS

BY

C. H. BERRY

(See Berry, "Humidity Computations," *Combustion*, Aug., Sept., Oct., 1934)

Atmospheric Humidity. The atmosphere is a mixture of air and water vapor. Dalton's law of partial pressures (for the mixture) and the ideal gas law (for each constituent) may safely be assumed to apply. The **total pressure** B (barometric pressure) is the sum of the **vapor pressure** p_v and the **air pressure** p_a.

The temperature of the atmosphere, as indicated by an ordinary thermometer, is the **dry-bulb temperature** t_d. If the atmosphere is cooled under constant total pressure, the partial pressures remain constant until a temperature is reached at which condensation of vapor begins. This temperature is the **dew-point** t_c (condensation temperature), and is the saturation temperature, or boiling point, corresponding to the actual vapor pressure p_v. If a thermometer bulb is covered with absorbent material, *e.g.*, linen, wet with distilled water and exposed to the atmosphere, evaporation will cool the water and the thermometer bulb to the **wet-bulb temperature** t_w. This is the temperature given by a psychrometer (see p. 374). The wet-bulb temperature lies between the dry-bulb temperature and the dew point. These three temperatures are distinct except for a saturated atmosphere, for which they are identical. For each of these temperatures, there is a corresponding vapor pressure. The actual vapor pressure p_v corresponds with the dew point t_c. The vapor pressures p_d and p_w, corresponding with t_d and t_w, do not represent pressures actually appearing in the atmosphere, but are used in computations.

Relative humidity r is the ratio of the actual vapor pressure to the pressure of saturated vapor at the prevailing dry-bulb temperature $r = p_v/p_d$. Within the limits of usual accuracy, this equals the ratio of actual vapor density to the density of saturated vapor at dry-bulb temperature, $r = \rho_v/\rho_d$.

Specific humidity s is the weight of water vapor (pounds or grains) per pound of air.

Molal humidity m is the weight of water vapor in mols per one mol of air. The molecular weight of water is 18, and the equivalent molecular weight of air is 28.95. The ratio $28.95/18 = 1.608$, or 1.61, with ample accuracy. The laws of Dalton and Avogadro state that the molal composition of a mixture is proportional to the distribution of partial pressures, wherefore $m = p_v/p_a = p_v/(B - p_v)$.

Air density ρ_a is the pounds of air in one cubic foot. **Vapor density** ρ_v is the pounds of vapor in one cubic foot. **Mixture density** ρ_m is the sum of these, *i.e.* the pounds of air plus vapor in one cubic foot.

Notation. The subscripts a, v, m, and f apply to air, vapor, mixture, and liquid water respectively. The subscripts d and w apply to conditions pertaining to the dry- and wet-bulb temperature, respectively.

Humidity Measurements. Many methods are in use; three are common. (1) The **dew-point** method measures the temperature at which condensation begins, whence vapor pressure is found from steam tables or means derived from them. Dew-point instruments are used in special cases, principally to calibrate other instruments. (2) The **hair hygrometer** measures relative humidity with accuracy sufficient for some purposes. For

Example. Initial conditions: $B = 29$ in. Hg; $t_d = 75$ F; $t_w = 65$ F; $p_v = 0.52$ in. Hg; $V = 1{,}500$ cu. ft.

Final conditions: $t_d = 45$ F.

Initial computed values: $r = 0.58$; $s = 0.0113$ lb vapor per lb air; $\rho_a = 0.0706$ lb air per cu ft; $W_a = 1500 \times 0.0706 = 106.0$ lb air; $h_m = 29.7$ Btu per lb air; $t_c = 60$ F.

Final computed values: $t_d = 45$ F; $p_v = 0.30$ in. Hg; $r = 1.0$; $s = 0.0065$ lb vapor per lb air; $\rho_a = 0.0754$ lb air per cu ft; $V = 106.0/0.0754 = 1{,}406$ cu ft; $h_m = 17.8$ Btu per lb air.

Liquid formed: $W_f = s_1 - s_2 = 0.0113 - 0.0065 = 0.0048$ lb liquid per lb air; $h_f = 50 - 32 = 18$ Btu per lb liquid (assuming that the liquid is drained out at an average temperature $t_f = 50$ F).

Heat abstracted: $q = h_{m1} - h_{m2} - W_f h_f = 29.7 - 17.8 - 0.0048 \times 18 = 11.8$ Btu per lb air; $Q = q \times W_a = 11.8 \times 106.0 = 1{,}250$ Btu.

Solution of the same problem *by chart* yields:

Initial readings: $r = 0.59$; $s = 76$ grains vapor per lb air $= 0.0108$ lb vapor per lb air; $v_a = 13.71$ cu ft per lb air; $\rho_a = 0.0729$; $W_a = 1500/13.71 = 109.4$ lb air; $\Sigma = 29.5$ Btu per lb air.

Final readings: $r = 1.0$; $s = 44$ grains vapor per lb air; $v_a = 12.84$ cu ft per lb air; $\rho_a = 0.0779$; $V = 109.4 \times 12.84 = 1{,}405$ cu ft; $\Sigma = 17.5$ Btu per lb air.

Liquid formed: $W_f = 76 - 44 = 32$ grains liquid per lb air $= 0.0046$ lb liquid per lb air; $h_f = 18$ (as above).

Heat abstracted: $q = \Sigma_1 - \Sigma_2 + s_1 h_{fw1} - s_2 h_{fw2} - W_f h_f = 29.5 - 17.5 + \frac{76}{7000}(65 - 32) - \frac{44}{7000}(45 - 32) - 0.0046 \times 18 = 12.2$ Btu per lb air; $Q = q \times W_a = 12.2 \times 109.4 = 1335$ Btu.

It is seen that the chart for $B = 29.92$ does not give correct results for a process conducted at $B = 29$ in. Hg.

Dehumidification may be accomplished in a **surface cooler**, in which the air passes over tubes cooled by brine or refrigerant flowing through them. The solution of this type of problem is most easily handled on the chart (see Fig. 6). Locate the point representing the state of the entering atmosphere, and draw a straight line to a point on the saturation curve ($r = 1.0$) at the temperature of the cooling surface. The final state of the issuing atmosphere is represented by a point on this line whose position on the line is determined by the heat abstracted by the cooling medium. This depends upon the extent of surface and the coefficient of heat transfer.

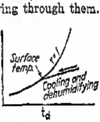

FIG. 6.—Cooling and Dehumidifying.

Adiabatic saturation, humidification, is conducted in a spray chamber through which atmosphere flows. A large excess of water is recirculated through spray nozzles, and evaporation is made up by a suitable water supply. After the process has been operating for some time, the water in the spray chamber will have been cooled to the temperature of adiabatic saturation, which differs from the wet-bulb temperature only because of radiation and velocity errors that affect the wet-bulb thermometer. No heat is added or abstracted; the process is adiabatic. The heat of vaporization for the water that is evaporated is supplied by the cooling of the air passing through the chamber. The wet-bulb temperature of the atmosphere is constant throughout the chamber (Fig. 7). If the chamber is sufficiently large, the issuing atmosphere will be saturated at the wet-bulb temperature of the entering atmosphere. That is, as the atmosphere passes through the chamber, t_w remains constant, t_d is reduced from its initial value to t_w, and t_c is increased from its initial value to t_w. In a chamber of commercial size, the action may

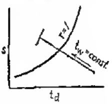

FIG. 7.—Evaporative Cooling. Adiabatic Saturation.

In Eqs. (1) and (2), two significant figures are ordinarily justifiable; in Eqs. (5) and (7), three significant figures; in Eqs. (3), (4), and (6), four decimal places.

Thermal results may be computed by the use of the enthalpy or of the sigma function. The **specific enthalpy** of air (above 0 F) is $h_a = 0.240t_d$ (up to 130 F the specific heat of air is 0.240; at higher temperatures it is larger). The specific enthalpy of low-pressure water vapor (saturated or superheated) is virtually independent of the vapor pressure and is a function of the temperature t_d. Values of h_v can be taken (to the nearest Btu per lb) from Table 1 of Keenan and Keyes, or may be computed to four significant figures by the following equation for the range of temperatures from −40 to 250 F.

$$h_v = 1062 + 0.44t_d, \text{ Btu per lb} = 0.1517 + 0.000063t_d \text{ Btu per grain} \quad (8)$$

The enthalpy of a mixture of air and vapor, in Btu per pound of air, is the sum of the enthalpy of 1 lb of air plus the enthalpy of the specific humidity (pounds or grains of vapor per pound of air)

$$h_m = h_a + s \times h_v = 0.240t_d + s \times h_v \quad (9)$$

The **sigma function** Σ has long been used under the name total heat. It differs from the enthalpy (see Carrier and Mackey, *Trans. A.S.M.E.*, Jan., 1937). The sigma function is the enthalpy of the mixture, Btu per lb air, minus the enthalpy at t_w of a weight of saturated liquid water equal to the specific humidity. The specific enthalpy of saturated liquid may be taken as $(t_w - 32)$ with ample accuracy, so that

140	187.9									

This method is not exact; results may be in error 1 or 2 deg F.

Example. Two atmospheres are to be mixed:

Atmosphere 1:

$t_d = 120$ F; $r = 0.90$; $V = 1$ cu ft; $B = 30$ in. Hg

Atmosphere 2:

$t_d = 0$ F; $r = 0.50$; $V = 1.5$ cu ft

By computation, $s_1 = 0.0726$ and $s_2 = 0.00041$ lb vapor per lb air; $\rho_{a1} = 0.0615$ and $\rho_{a2} = 0.0853$ lb air per cu ft.

Since volume times density equals total weight,

$$W_{a1} = 1 \times 0.0615 = 0.0615 \text{ lb air}; \quad W_{a2} = 1.5 \times 0.0853 = 0.1278 \text{ lb air};$$
$$W_{a3} = 0.0615 + 0.1278 = 0.1893 \text{ lb air};$$

$$s_3 = \frac{0.0615 \times 0.0726 + 0.1278 \times 0.00041}{0.1893} = 0.0238 \text{ lb vapor per lb air}$$
$$= 167 \text{ grains vapor per lb air}$$
$$t_{d3} = \frac{0.0615 \times 120 + 0.1278 \times 0}{0.1893} = 39 \text{ F}$$

By means of a draftsman's triangle, locate the point on the chart for which $t_d = 39$ and $s = 167$ grains of vapor per pound of air. This point falls far above the saturation curve. With a second triangle, a line is located passing through this point and running parallel to the lines of constant wet-bulb temperature; this line intersects the saturation curve at $t_d = 71$, which is the true final temperature of the mixture, and the specific humidity is 114 grains of vapor per pound of air. The difference in specific humidities is the weight of condensate, $167 - 114 = 53$ grains of condensate per pound of air.

If the mixing proportions are not given, but the final temperature is prescribed, the line is drawn between the two initial points, and its intersection with the desired final temperature is noted. A reversal of the foregoing method of computing will yield the mixing proportions.

The **cooling tower** is a chamber in which outdoor atmosphere flows through a spray of entering hot water, which is to be cooled. The temperature of the water is reduced in part by the warming of the air, and in greater part by the evaporation of a portion of the water. The atmosphere enters at given conditions and emerges at a higher temperature and usually saturated ($r = 1$). It is commonly possible to cool the water below the temperature of the entering air, often to about halfway between t_d and t_w. The volume of atmosphere per pound of entering water and the weight of water evaporated are to be computed.

Example. A cooling tower is to receive water at 120 F and atmosphere at $t_d = 90$, $t_w = 80$, whence $p_v = 0.92$, $s = 0.0196$ lb vapor per lb air, $\rho_a = 0.0702$ lb air per cu ft, and $h_m = 43.2$. The water is to be cooled to 85 F. What volume of atmosphere must be passed through the tower, and what weight of water will be lost by evaporation?

The issuing atmosphere will be assumed to be saturated at 115 F. Then $t_d = 115$ F, $p_v = 3.0$ in. Hg, $s = 0.0690$ lb vapor per lb air, $\rho_a = 0.0623$ lb air per cu ft, and $h_m = 104.4$ Btu per lb air.

The two unknowns are the weight of air to be passed through the tower and the weight of water to be evaporated. The two equations are the water-weight balance and the enthalpy balance (the steady-flow equation for zero heat transfer to or from outside). Assume that 1 lb water enters, of which x lb are evaporated. The water-weight balance $1 + W_a s_1 = 1 - x + W_a s_2$, becomes, $x = W_a(s_2 - s_1) = W_a(0.0690 - 0.0196) = 0.0494W_a$. The enthalpy balance $1 \times (120 - 32) + W_a h_{m1} = (1 - x)(85 - 32) + W_a h_{m2}$ becomes, $88 + 43.2W_a = 53(1 - x) + 104.4W_a$; whence, $53x = 53 - 88 + W_a(104.4 - 43.2) = -35 + 61.2W_a$.

Solving these simultaneous equations, $x = 0.0295$ lb water evaporated per pound of water entering and $W_a = 0.597$ lb air per pound water entering.

In an **evaporative condenser**, vapor is condensed within tubes that are cooled by the evaporation of water flowing over the outside of the tubes;

Nomenclature and Units

The units are based on feet, pounds, hours, degrees Fahrenheit, and Btu. Any other consistent set may be used in the dimensionless relations given, but for the dimensional equations the units of this table must be used.

A = area of heat-transfer surface, sq ft.
A_i = inside area.
A_o = outside area.
A_m = average value of A, sq ft.
a = an empirical dimensionless constant.
a' = cost of work delivered to fluid, dollars per foot-pound.
B = ratio of equivalent frictional length to that of the straight tubes, dimensionless.
b = fixed charges on insulation, dollars per year per sq ft per in. thickness.
b' = fixed charges on exchanger, dollars per hr per sq ft of inside surface.
C_p = specific heats at constant pressure, Btu per lb per deg F.
D = diameter, ft.
D_o = outside diam, ft.
D_i = inside diam, ft.
D' = diameter, in.
D'_o = outside diam, in.
D'_i = inside diam, in.
e = base of natural logarithms, 2.718.
G = mass velocity, equals w/S, lb per hr per sq ft of cross section occupied by fluid.
G_{max} = mass velocity through minimum free area in a row of pipes normal to the fluid stream, lb per hr per sq ft.
g_c = conversion factor, equal to 4.18×10^8 (mass lb)(ft)/(force lb)(hr)^2.
g_L = acceleration due to gravity, 4.18×10^8 ft per hr per hr.
h = local individual coefficient of heat transfer, equals $dq/dA\Delta$, Btu per hr per sq ft per deg F diff.
$h_c + h_r$ = combined coefficient by conduction, convection, and radiation between surface and surroundings.
h_m = mean value of h for entire surface, based on Δ_m.
$h_{a.m.}$ = average h, arbitrarily based on arithmetic-mean temperature difference.
h_s = heat transfer coefficient through scale deposits.
k = thermal conductivity, Btu per hr per sq ft per unit temperature gradient, deg F per ft.

entering and leaving atmospheres. Its specific enthalpy at the observed or assumed temperature of supply or removal t_f is

$$h_f = t_f - 32 \text{ Btu per lb of liquid} \tag{11}$$

Since all air-conditioning apparatus involves steady-flow processes, thermal results are computed by the steady-flow equation, written for 1 lb of air. No work term appears, for the compression work done by a fan is usually negligible. Using subscript 1 for entering atmosphere and liquid water, and for heat supplied; and 2 for departing atmosphere and water, and for heat abstracted; the equation becomes

$$h_{m1} + W_{f1}h_{f1} + q_1 = h_{m2} + W_{f2}h_{f2} + q_2 \text{ Btu per lb air} \tag{12}$$

Usually either or both values of W_f and q will be zero.

In terms of the sigma function, the steady-flow equation becomes

$$\Sigma_1 + s_1(t_{w1} - 32) + W_{f1}h_{f1} + q_1 = \Sigma_2 + s_2(t_{w2} - 32) + W_{f2}h_{f2} + q_2 \text{ Btu per lb air} \tag{13}$$

Unit processes involved in air conditioning include heating and cooling an atmosphere above its dew point, cooling below the dew point, adiabatic saturation, and mixing of two atmospheres. These, in various sequences, make it possible to start with any given atmosphere and produce an atmosphere of any required characteristics.

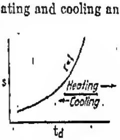

FIG. 4.—Heating or Cooling above the Dew Point.

Heating and cooling above the dew point entails no condensation of vapor. Barometric pressure and composition being unaltered, partial pressures remain constant. The process is represented in Fig. 4.

Example. Initial conditions: $B = 28$ in. Hg; $t_d = 60$ F; $t_w = 50$ F; $p_v = 0.26$ in. Hg; $V = 1{,}200$ cu ft.

Final conditions: $t_d = 82$ F.

Initial computed values: $r = 0.50$; $s = 0.0058$ lb vapor per lb air; $\rho_a = 0.0707$ lb air per cu ft; $W_a = V \times \rho_a = 1200 \times 0.0707 = 84.9$ lb air; $h_m = 20.7$ Btu per lb air.

Final computed values: p_v, s, and W_a are unaltered; $r = 0.24$; $\rho_a = 0.0879$ lb air per cu ft; $V = W_a/\rho_a = 84.9/0.0670 = 1250$ cu ft; $h_m = 20.1$ Btu per lb air.

Heat added: $q = h_{m2} - h_{m1} = 26.1 - 20.7 = 5.4$ Btu per lb air; $Q = q \times W_a = 5.4 \times 84.9 = 458$ Btu.

The *solution* of this same problem *from chart readings* will indicate the discrepancy to be expected from the departure of the barometric pressure from that for which the chart is constructed (29.92 in. Hg).

Initial readings: $r = 0.49$; $s = 38$ grains vapor per lb air $= 0.0054$ lb vapor per lb air; $v_a = 13.21$ cu ft per lb air; $\rho_a = 0.0757$ lb air per cu ft; $W_a = V/v_a = 1200/13.21 = 90.8$ lb air; $\Sigma = 20$ Btu per lb air.

Final readings: $r = 0.24$; $v_a = 13.77$; $\rho_a = 0.0726$; $V = 90.8 \times 13.77 = 1{,}250$ cu ft; $t_w = 59$ F; $\Sigma = 25.4$ Btu per lb air.

Heat added: $q = \Sigma_2 - \Sigma_1 + s \times (t_{w2} - t_{w1}) = 25.4 - 20.0 + 38(59 - 50)/7000 = 5.4$ Btu per lb air; $Q = q \times W_a = 5.4 \times 90.8 = 490$ Btu.

It is evident that the chart gives substantially correct values for the final relative humidity and total volume and for the heat added per pound of air. The weight of air, however, is in error by about 7 percent, *i.e.*, almost in proportion to the barometric pressure, and in consequence the aggregate heat added is in error to this same extent.

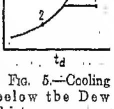

FIG. 5.—Cooling below the Dew Point.

Cooling below the dew point or dehumidification, entails condensation of vapor; the final atmosphere will be saturated, liquid will appear; see Fig. 5.

μ_w = viscosity at wall temperature, lb per hr per ft.
ρ = density, lb per cu ft.
ρ_∞ = density of stream of great depth, lb per cu ft.

Preliminary Statements. There are three methods by which heat may be propagated or conveyed from one place to another.

1. By **conduction.** Heat passing from one part of a body to another part of the same body, or from one body to another in physical contact with it, without displacement of the particles of the body, is said to flow by conduction.

2. By **convection.** Convection is the transfer of heat from one place to another within a fluid (gas or liquid) by the mixing of one portion of the fluid with another.

3. By **radiation.** All bodies give off heat in the form of radiant energy, which is propagated in all directions as a wave motion in the ether. Radiation falling upon a body is absorbed by it either wholly or in part. If two bodies, one hotter than the other, are placed within an enclosure, there is a continual interchange of energy between them. The hotter body radiates more energy than it absorbs, the colder body absorbs more than it radiates. Even after equilibrium of temperature is established the process continues, each body radiating and absorbing energy.

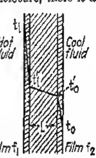

FIG. 1.—Temperature Gradients in Heat Flow through a Wall.

Phenomena of Heat Transmission. In the cases of heat transmission that usually occur in practice—in boilers, condensers, the cooling of engine cylinders, etc. —heat is transmitted from one fluid to another through a wall separating the two. The character of the process is shown in Fig. 1. At the surface of the plate, there is a film of the hot fluid of indefinite thickness. This film offers a considerable resistance to the transmission, as shown by the temperature difference $t_i - t'_i$ through it. A corresponding film on the other side of the plate offers resistance measured by the temperature drop $t'_o - t_o$. Let dq denote the rate of heat transmission in Btu per hr through the surface area dA_i sq ft. Then, for film f_1, $dq = h_i\, dA_i(t_i - t'_i)$; for the plate, $dq = (k/L)dA'(t'_i - t'_o)$; for the film f_2, $dq = h_o\, dA_o(t'_o - t_o)$.

The terms h_i and h_o are the **film coefficients** of the films f_1 and f_2, respectively, and k is the thermal conductivity of the plate; $h_o\, dA_o$ and $h_i\, dA_i$ are the **thermal conductance** of the films and $k\, dA'/L$ is the conductance of the plate. Eliminating the surface temperatures t_i' and t_o' from the equations, the equation is obtained for steady flow through several resistances in series:

$$dq = \frac{t_i - t_o}{(1/h_i\, dA_i) + (L/k\, dA') + (1/h_o\, dA_o)} \cdots \tag{1}$$

The terms $1/h_i\, dA_i$ and $1/h_o\, dA_o$ are the **thermal resistances** of the films, and $L/k\, dA'$ is the resistance of the plate. In the expression $dq = U dA(t_i - t_o)$, the total thermal resistance $1/U dA$ to the flow is the sum of the separate resistances.

$$1/U dA = (1/h_i\, dA_i) + (L/k\, dA') + (1/h_o\, dA_o) + (1/h_s\, dA) \cdots \tag{2}$$

$U dA$ is the over-all conductance of the two films, a scale deposit, and the plate, and U is the corresponding over-all coefficient.

terminate somewhat short of this, the precise end point being determined by the duration and effectiveness of contact between air and spray water. In any case, the weight of water evaporated equals the increase in the specific humidity of the atmosphere.

Example. Initial conditions: $B = 30$ in. Hg; $t_d = 78$ F; $t_w = 55$ F; $r = 0.20$; $s = 28$ grains vapor per lb air.
Final condition: $t_d = t_w = 55$ F; $r = 1.0$; $s = 64$ grains vapor per lb air.
Water evaporated: $s_2 - s_1 = 64 - 28 = 36$ grains water per lb air.

The design of the spray chamber to produce this result is necessarily based upon experience with like apparatus previously built.

In practice, the spray chamber is preceded and followed by heating coils, the first to warm the entering atmosphere to the desired value of t_w, determined by the prescribed final specific humidity, the second to warm the issuing atmosphere to the desired temperature, and simultaneously to reduce its relative humidity to the desired value.

The spray chamber that is used for adiabatic saturation, humidification, in winter may be used for dehumidification in summer by supplying the spray nozzles with refrigerated water instead of recirculated water. In this case, the issuing atmosphere will be saturated at the temperature of the spray water, which will be held at the desired dew point. Subsequent heating of the atmosphere to an acceptable temperature will simultaneously reduce the relative humidity to the desired value.

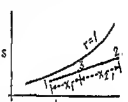

FIG. 8.—Mixing Two Atmospheres. (Final Point below the Saturation Curve.)

Mixing Two Atmospheres. In recirculating ventilation systems, two atmospheres (1 and 2) are mixed to form a third (3). The state of the final atmosphere is readily found graphically on the psychrometric chart (see Fig. 8). Locate the points 1 and 2 representing the states of the initial atmospheres. Connect these points by a straight line. Locate a point that divides this line into segments inversely proportional to the weights of air in the respective atmospheres. The division point represents the state of the final mixture, so long as it falls below the saturation curve ($r = 1$). If the final point falls above the saturation curve, as in Fig. 9, condensation will ensue, and the true final point 4 is found by drawing a line from the apparent point 3, parallel to the lines of constant wet-bulb temperature, to its intersection with the saturation curve. From all the points involved, readings of specific humidity may be taken, including point 3 when it falls above the saturation curve, and in this case the difference between s_3 and s_4 will be the weight of condensate, pounds per pound air.

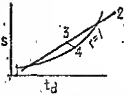

FIG. 9.—Mixing Two Atmospheres. (Final Point above the Saturation Curve.)

If the chart is sectional and the two points do not fall in the same section, or in any case in which it is preferred, the same method may be carried out arithmetically. The state of the final atmosphere is characterized by a specific humidity and a dry-bulb temperature which are the weighted averages of the like quantities for the original atmospheres, the weighting factors being the respective weights of air.

$$W_{a3} = W_{a1} + W_{a2} \tag{14}$$
$$W_{a3}s_3 = W_{a1}s_1 + W_{a2}s_2 . \tag{15}$$
$$W_{a3}t_{d3} = W_{a1}t_{d1} + W_{a2}t_{d2} \tag{16}$$

CONDUCTION

Thermal Conductivity. The basic Fourier conduction law is $dq = -k\,dA(dt/dL)$, which states that the steady rate dq of heat conduction is proportional to the cross-sectional area dA normal to the direction of flow, and to the temperature gradient $-dt/dL$ along the conduction path. The number k in this expression is called the "true" thermal conductivity of the material of the plate. The thermal conductivity of a substance may be

the water evaporates into the atmosphere. The computation of results is similar to that for the cooling tower.

Combustion Computations. The total weight of water vapor in the flue-gas mixture is the sum of that arriving with the air and that resulting from the combustion of hydrogen and hydrocarbons. The weight of dry flue gases is computed from the chemical equations. From Eq. (4), the vapor pressure in the flue gas can be computed, and from this the dew point of the flue gas can be estimated on the assumption that the dry gases do not influence the vapor pressure. If the fuel contains an appreciable amount of sulphur, the flue gas will carry enough sulphur oxides to change the result markedly. The vapor pressure of sulphurous acid (SO_2 dissolved in water) is less than the vapor pressure of pure water; that of sulphuric acid (SO_3 dissolved in water) is much more so. Accordingly, the dew point will be higher. The dew point of flue gas, neglecting sulphur oxides, often falls not far from 120 F. Actual dew points as high as 250 F have been observed in flue gas arising from high-sulphur coal.

The conductivity of air as a function of temperature is given by the relation,

$$k_T = 0.0129[717/(T + 225)](T/492)^{3/2}$$

where T is temperature in deg F absolute. This relation is valid from −312 to 212 F. Values of the conductivities of air and steam at a series of temperatures are given below, those at 300 F being extrapolated.

For t (deg F)	32	50	100	200	300
k (for air)	0.0129	0.0132	0.0143	0.0162	0.0180

$k_m = \frac{1}{t_1 - t_2}\int_1^2 k\, dt.$

k_f = k at the "film" temperature, $t_f = (t + t_w)/2$.
L = thickness of conductor, ft.
N = length of heat-transfer surface, heated length, ft.
n = number of rows in a vertical plane.
Q = quantity of heat, Btu.
q = rate of heat flow, Btu per hr.
R = thermal resistances, $1/UA$, $1/hA$, $1/(h_c + h_r)A_o$.
r = radius, ft.
S = cross section, filled by fluid, in plane normal to direction of fluid flow, sq ft.
T = temperature, deg $R = t + 460$.
T_1, T_2 = inlet and outlet bulk temperatures, respectively, of warmer fluid, deg F.
t = bulk temperature (based on heat balance), deg F.
t_w = wall temperature, deg F.
t_1, t_2 = inlet and outlet bulk temperatures of colder fluid, deg F.
t_∞ = temperature of stream of great depth, ambient temperature, F.
t_i, t_o = temperatures of fluid inside and outside, deg F.
t_f = $(t + t_w)/2$.
U = over-all coefficient of heat transfer, Btu per hr per sq ft per deg F; U_i, U_o based on inside and outside surfaces, respectively.
V_s = average velocity, volumetric rate divided by cross section filled by fluid, fps.
V_{sm} = maximum velocity, through minimum cross section, fps.
V_∞ = velocity of stream of great depth, ft per hr.
w = mass rate of flow per tube, lb per hr per tube.
Z = $(T_1 - T_2)/(t_2 - t_1)$.
α = a dimensional constant.
β = volumetric coefficient of thermal expansion, having units of reciprocal of Fahrenheit absolute temperature.
Γ = mass rate of flow, lb/(hr)(ft of wetted periphery measured on a plane normal to direction of fluid flow); $= w/\pi D$ for a vertical and $w/2N$ for a horizontal tube.
Δ = temp diff, deg F.
$\Delta_{a.m.}, \Delta_{l.m.}$ = arithmetic and logarithmic means of terminal temperature differences, respectively, deg F.
Δ_m = true mean value of the terminal temperature differences, deg F.
Δ_o = over-all temp diff, deg F.
Δ_s = temperature difference between surface and surroundings, deg F.
θ = time, hr.
λ = latent heat (enthalpy) of vaporization, Btu per lb.
μ = viscosity at bulk temperature, lb per hr per ft; equals 2.42 times centipoises; equals 106,000 times viscosity in (lb force)(sec)/sq ft.
μ_f = viscosity, lb per hr per ft, at arithmetic mean of wall and fluid temperatures.

$$\frac{1}{UA} = \frac{1}{h_iA_i} + \frac{L}{kA_m} + \frac{1}{h_sA_s} + \frac{1}{h_oA_o} \tag{5a}$$

and the values of h are obtained from the following pages. For the more complex cases of multipass and cross flow, Δ_m is given by Fig. 2. The shell-side fluid is assumed to be well-mixed by suitable baffles.

Example. Assume an exchanger in which the hot fluid enters at 400 F and leaves at 200 F; the cold fluid enters at 100 F and leaves at 200 F. Assuming U independent of temperature, what will be the true mean temperature difference from hot to cold fluid, (1) for counterflow and (2) for a reversed current apparatus with one well-baffled pass in the shell and two passes in the tubes?

1. With counterflow, the terminal differences are $400 - 200 = 200$ F and $200 - 100 = 100$ F; the logarithmic mean difference is $100/(2.3)(0.301) = 144$ F.

2. $Z = (400 - 200)/(200 - 100) = 2$, $X = (200 - 100)/(400 - 100) = \frac{1}{3}$; from section A of Fig. 2, $Y = 0.80 = \Delta_m/144$; $\Delta_m = 115$ deg.

If one of the temperatures remains constant, as in a condenser or in an evaporative cooler, Eq. (5) applies for parallel flow, counterflow, reversed current, and cross flow.

If U varies considerably with temperature, the apparatus should be considered to be divided into stages, in each of which variation of U with temperature or temperature difference is linear. Then for parallel or counterflow operation, the following relation may be applied to each stage:

$$q = A(\Delta_{o1}U_2 - \Delta_{o2}U_1)/\log_e(\Delta_{o1}U_2/\Delta_{o2}U_1) \tag{5b}$$

FILM COEFFICIENTS

The important physical properties, which affect film coefficients (see p. 386), are thermal conductivity, viscosity, density, and specific heat. Obviously, these factors depend upon the temperature level. Factors within the control of the designer include velocity, shape, and arrangement of the heating surface. With forced flow of gases or water, under the conditions usually met in practice, the flow is turbulent in character (see p. 264), and under these conditions the film coefficient can be greatly increased by increasing the velocity of the fluid at the expense of a greater power requirement. For a given velocity and fluid, the film coefficient depends upon the direction of flow of fluid relative to the heating surface. With free or natural convection, for a given fluid and arrangement of surface, the film coefficient depends upon physical properties such as viscosity, density, thermal conductivity, and coefficient of expansion and upon temperature difference, but the convection currents ordinarily are not expressed in terms of definite fluid velocities. With forced convection at low rates of flow, particularly with viscous fluids such as oils, laminar motion may prevail and the film coefficient is almost independent of fluid velocity, being determined primarily by free convection factors. In any event, the film coefficients h are correlated in terms of dimensionless groups of the controlling factors.

The following simplified dimensional equations for film coefficients are recommended as approximations, and require the use of the units given on p. 384:

Turbulent Flow of Gases inside Clean Tubes.

$$h_m = 0.024C_pG^{0.8}/(D'_i)^{0.2} \tag{6a}$$

Natural Convection. For heat loss from surfaces by conduction and convection to air at atmospheric pressure and ordinary temperatures, the coefficients are given by the following equations (using the units of p. 384).

Horizontal pipes, long vertical pipes:

$$h_m = 0.42(\Delta_s/D')^{0.25} \qquad (11a)$$

Vertical plates less than 2 ft high:

$$h_m = 0.28(\Delta_s/N)^{0.25} \qquad (11b)$$

Vertical plates more than 3 ft high:

$$h_m = 0.3\Delta_s^{0.25} \qquad (11c)$$

Horizontal plates, facing upward:

$$h_m = 0.38\Delta_s^{0.25} \qquad (11d)$$

Horizontal plates, facing downward:

$$h_m = 0.2\Delta_s^{0.25} \qquad (11e)$$

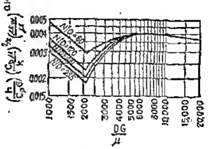

FIG. 3.—Heating and Cooling of Viscous Oils Flowing inside Tubes. (The Curves for DG/μ below 2100 Are Based on Eq. 10.)

For heat transfer by natural convection between liquids and submerged heating coils, data are scarce. As a conservative approximation, the following dimensionless equation, based on heat transfer from single horizontal pipes to liquids or gases, may be used:

$$h_m D/k_f = 0.47[(D^3\rho^2{}_f g_L/\mu^2{}_f)(\beta\Delta_s)(C_p\mu_f/k_f)]^{0.25} \qquad (12)$$

For a given film temperature, this reduces to $h_m = a(\Delta_s/D')^{0.25}$. For $t_f = 150$ F, a is 25 for water and 16 for aniline or 98 percent sulphuric acid.

Economic Velocity. In many heat exchangers, the over-all coefficient follows the relation $U = \alpha G^n$ and the friction factor f (see p. 359) follows the rule $f = a(\mu/DG)^m$. As shown by Drew, Hottel, and McAdams (*Trans. Am. Inst. Chem. Eng.*, 32, 1936, pp. 289–291) the total costs (which vary with G) are a minimum when the optimum velocity is employed:

$$G_{opt} = [2n/(3 - m - n)][(g_c\rho^2 b'/a'fB)]^{1/3} \qquad (12a)$$

The corresponding optimum ratio $(x_p/x_{f.c.})_{opt}$ of power cost to fixed charges on the exchanger is given in terms of the exponents by

$$(x_p/x_{f.c.})_{opt} = n/(3 - m - n) \qquad (12b)$$

The corresponding optimum total costs, $x_p + x_{f.c.}$ except for the cost of the heat itself, is given by

$$(x_p + x_{f.c.})_{opt} = \frac{(3 - m)b'}{(3 - m - n)U_{opt}\Delta_e} \qquad (12c)$$

For the **optimum temperature difference** for recovering waste heat see Lewis, Ward, and Voss (*Ind. Eng. Chem.*, 16, 1924, pp. 467–468).

Condensing Vapors. When condensing a single pure vapor, saturated or superheated, the condensate wets the tube and film-type condensation is obtained. The rate of heat transfer q equals $h_m A\Delta_m$ where Δ_m is the mean difference between the saturation temperature and the temperature of the surface of the tube. So long as the condensate flows in streamline motion ($4\Gamma/\mu < 2100$) the following dimensionless equations may be used:

For **horizontal tubes**;

$$h_m D/k = 0.73(D^3\rho^2\lambda g_L/k\mu_f n\Delta)^{0.25} = 0.76(D^3\rho^2 g_L/\mu_f\Gamma)^{1/3} \qquad (13)$$

defined *as the quantity of heat* (Btu) *that flows in a unit of time* (1 hr) through unit area of plate (1 sq ft) of unit thickness (1 ft) having unit difference of temperature (1 deg F) between its faces. The mean thermal conductivity k_m is given the relation, for steady flow of q Btu per hr through a wall having mean surface area A_m sq ft and a thickness of L ft:

$$q = k_m A_m (t'_i - t'_o)/L, \quad \text{or} \quad k_m = qL/A_m(t'_i - t'_o) \tag{3}$$

It will be observed that the units of the conductivity k contain the element of thickness, while the coefficient h does not. The thermal conductivity of a given material varies with temperature and

$$k_m(t'_i - t'_o) = -\int_{t'_i}^{t'_o} k\, dt$$

Over moderate ranges, k varies linearly with t', and hence k_m may be evaluated at the arithmetic mean of t'_i and t'_o. The numerical value of the mean area

A_m, in $qL/A_m = q\int dL/A$, depends on the shape of the conductor. For flat plates, $A_m = A_i = A_o$; for the hollow cylinder,

$$A_m = (A_i - A_o)/\log_e (A_i/A_o) \tag{4}$$

and for the hollow sphere, $A_m = \sqrt{A_i A_o}$. For more complex shapes, a shape factor may be evaluated by a graphical procedure (Awbery and Schofield, *Proc. 5th Intern. Congr. Refrig.*, 3, 1929, pp. 591–610).

The thermal conductivity of different materials varies greatly. For metals and alloys k is high, while for certain insulating materials, as asbestos, cork, and kapok, k is very low. In general, **k varies with the temperature.** In the case of metals, k usually decreases with rising temperature, while for most other substances the reverse is true. Tables 1 to 7, collected from various sources, give values of thermal conductivity. For refractories, see p. 731; for pipe coverings, p. 953; for ship construction materials, p. 1524. Conversion factors for various units are given on p. 81.

thermal conductivity which forms on the surface. For a given liquid and boiling pressure, the nature of the surface may substantially influence the flux at a given Δ_o, Table 9. These data may be used as rough approximations for a bank of submerged tubes. Film coefficients for scale deposits are given in Table 10.

Table 9. Maximum Flux and Corresponding Over-all Temperature Difference for Liquids Boiled at 1 Atm with a Submerged Horizontal Steam-heated Tube

Distilled water	..	..	230	85	350	75	410	150

The effect of reducing the boiling temperature by use of vacuum is illustrated by Fig. 5.

For **forced-circulation evaporators**, vapor binding is also encountered. Thus with liquid benzene entering a 4-pass steam-jacketed pipe at 0.9 fps, up to the point where 60 percent by weight was vaporized, the maximum flux of 60,000 Btu per hr per sq ft was obtained at an over-all temperature difference of 60 F; beyond this point, the coefficient and flux decreased rapidly,

CONDUCTION AND CONVECTION

Mean Temperature Difference. The basic equation for any steadily operated heat exchanger is $dq = U\Delta_0\, dA$, in which U is the over-all coefficient (p. 386), Δ_0 is the over-all temperature difference between hot and cold fluids, and dq/dA is the local rate of flow per unit surface. In order to apply this relation to a finite exchanger, it is necessary to integrate it. The assumptions usually made are constant U, constant mass rates of flow, no changes in phase, constant specific heats, and negligible heat losses. The resulting equation for parallel or countercurrent flow of fluids is

$$q = UA\Delta_m = UA(\Delta_{01} - \Delta_{02})/\log_e (\Delta_{01}/\Delta_{02}) \tag{5}$$

in which Δ_m is the logarithmic mean of the terminal temperature differences, Δ_{01} and Δ_{02}, between hot and cold fluid. The value of UA is evaluated from the resistance concept

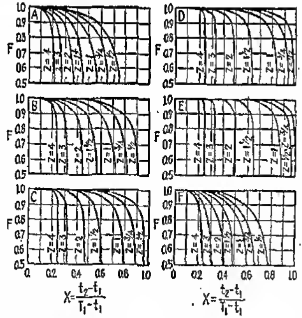

FIG. 2.—*A*, One Shell Pass and Two Tube Passes; *B*, Two Shell Passes and Four Tube Passes; *C*, Three Shell Passes and Six Tube Passes; *D*, Four Shell Passes and Eight Tube Passes; *E*, Six Shell Passes and Twelve Tube Passes; *F*, Cross flow, One Shell Pass and One Tube Pass.

$$F = \text{ordinate} = \frac{\text{true mean temperature difference}}{\text{logarithmic-mean temperature difference for counterflow}}$$

For the other symbols see p. 384.

Examples of Heat Transmission

Building Constructions (see p. 1524). The coefficients given by Harding and Willard are used as the basis of the following figures. As an example of the method of computation, consider a brick wall 13 in. in thickness. The coefficients are $h_1 = 1.4$; $h_2 = 4.2$, $k = 5/12$; hence $R = (1/1.4) + (13/5) + (1/4.2) = 3.6$ and $U = 1/3.6 = 0.28$ Btu per sq ft per hr per deg F.

Table 12. Transmission Coefficients for Various Building Constructions

Construction	Thickness, in.	U	Construction	Thickness, in.	U
Plain brick wall: $h_1 = 1.4$, $h_2 = 4.2$, $k = 5/12$.	9	0.36	Concrete[a]: $h_1 = 1.3$, $h_2 = 3.9$, $k = 5/12$.	2	0.78
	13	0.28		3	0.71
	18	0.22		4	0.66
	24	0.17		6	0.56
Brick wall + air space....	9	0.22	Windows: $h_1 = 1.5$, $h_2 = 4.5$.	Single	1.13
Brick furred and plastered.	13	0.19		Double	0.45
	18	0.16		Triple	0.28

			Wood + air space.......	....	0.20

[a] For 3 in. concrete covered with slag roofing, deduct 10 percent.

Heat Transmission through Pipe Insulation. (McMillan, *Trans. A.S.M.E.*, 1915.) For any number of layers of insulation on any size of pipe, Eqs. (4), (5), and (14) combine to give

$$\frac{q_o}{A_o} = \frac{\Delta_o}{\dfrac{r_o}{k_1}\log_e\dfrac{r_2}{r_1} + \dfrac{r_o}{k_2}\log_e\dfrac{r_3}{r_2} + \cdots + \dfrac{1}{h_c + h_r}} \tag{15}$$

where q_o/A_o is the Btu lost per hr per sq ft of outer surface of the last layer; Δ_o is the over-all temperature difference (deg F) between pipe and air; r_o

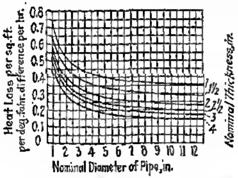

FIG. 6.—Variation with Pipe Size of Coefficient of Heat Transmission through a Given Thickness of Insulation.

is the radius, ft, of the outer surface; r_1 is the outside radius, ft, of the pipe, $r_2 = r_1 +$ thickness of first layer of insulation, ft; $r_3 = r_2$ plus the thickness of second layer, etc.; and k_1, k_2, k_3, etc., are the conductivities of the respective layers. Values of $(h_c + h_r)$ are given on p. 397 for indoor conditions and for various wind velocities. For average indoor conditions, $h_c + h_r$ is often taken

Turbulent Flow of Water inside Clean Tubes.

$$h_m = 160(1 + 0.012t_f)V_s^{0.8}/(D'_i)^{0.2} \tag{6b}$$

Turbulent Flow in Annular Spaces. Use Eqs. (6a) or (6b) with D' taken as the clearance, inches, and base the heat transfer area on that actually heated or cooled.

Water in Coiled Pipes. Multiply h_m for the straight pipe, Eq. (6b), by the factor $1 + (3.5D_i/D_c)$, where D_i is the inside diameter of the pipe and D_c is that of the coil.

Gas Flow Normal to a Single Tube (when $DG/\mu_f > 1000$).

$$h_m = 0.37C_pG^{0.56}/(D'_o)^{0.44} \tag{7}$$

Gas Flow Normal to a Bank of Staggered Tubes.

$$h_m = 0.031C_pT^{0.3}G_m^{2/3}/(D'_o)^{1/3} \tag{8}$$

Water Flow Normal to a Bank of Staggered Tubes.

$$h_m = 370(1 + 0.0067t_f)V_{sm}/(D'_o)^{0.4} \tag{8a}$$

For baffled exchangers, to allow for leakage of fluids around the baffles, use 60 percent of the values of h_m from Eqs. (8) and (8a); for tubes in line, deduct 25 percent from the values of h_m given by Eqs. (8) and (8a).

Water Flow in Layer Form over Horizontal Tubes.

$$h_{a.m.} = 150(\Gamma/D'_o)^{1/3} \tag{9}$$

for Γ ranging from 100 to 1,000 lb of water per hr per ft.

Water Flow in Layer Form down Vertical Tubes.

$$h_m = 120\Gamma^{1/3} \tag{9a}$$

Table 8. Values of h_m for Heating and Cooling, Forced Convection
(D'_o = 1.31 in., D'_i = 1.05 in.)

Fluid and arrangement	t_f, deg F	Velocity		Btu per hr per sq ft per deg F	Eq. No.
		Fps[a]	Lb per hr per sq ft		
Air inside tubes	...	$V_s = 31.8$,	$G = 8600$	8.0	6a
Air normal to staggered tubes	170	$V_s = 7.42$,	$G_m = 2000$	7.5	8
Water inside tubes	100	$V_s = 5.0$,	$G = 1.12 \times 10^6$	1260	6b
Water normal to staggered tubes	100	$V_s = 2.0$,	$G_m = 0.448 \times 10^6$	800	8a
Trickle cooler, water	...	Γ = 100 lb per hr per ft		640	9
Falling water film, vertical tube	...	Γ = 1,000 lb per hr per ft		1000	9a

[a] Velocity in fps at 70 F and 1 atm = $G/3600\ \rho$.

Coefficients for scale deposits are given in Table 10.

Streamline Flow. With liquids of high viscosity, such as viscous oils flowing at values of DG/μ below 2100, streamline flow ensues, and the coefficient of heat transfer is given by the dimensionless equation

$$h_{a.m.}D/k = 2.0(wC_p/kN)^{1/3}(\mu/\mu_w)^{0.14} \tag{10}$$

or

$$(h_{a.m.}/C_pG)(C_p\mu/k)^{2/3}(\mu_w/\mu)^{0.14} = 1.85(D/N)^{1/3}(DG/\mu)^{-2/3} \tag{10a}$$

As the value of DG/μ increases from 2100 to 7000, the effect of heated length upon h, as shown in Fig. 3, diminishes and finally becomes zero.

RADIANT-HEAT TRANSMISSION

BY

HOYT C. HOTTEL

A heated body loses energy continuously by radiation. The quantity emitted depends on the shape, size, and, particularly, the temperature of the body and is independent of the nature of its surroundings. This emitted radiation is capable of passage to a distant body where it may be absorbed, reflected, scattered, or transmitted. Most problems of energy transfer by thermal radiation may conveniently be discussed under one of the following heads: radiant-heat exchange between the surfaces of solids separated by nonabsorbing mediums; radiation from flames and gases; radiation from clouds of particles; the combined action of all these mechanisms in a furnace chamber.

Radiant-heat Exchange between the Surfaces of Solids

Thermal radiation from the surface of a solid is, for engineering purposes, best expressed as a ratio to the radiation from a so-called ideal **radiator** or **black body**. The characteristic properties of a black body are that it absorbs all the radiation incident on its surface and reflects, transmits, or scatters none; that the quality and quantity of the radiation that it emits are completely determined by its temperature, an increase in temperature producing an increase both in total radiation and in the fraction emitted in the short-wave region of the spectrum. The total radiation q from a black surface of area A and absolute temperature T is given by the **Stefan-Boltzmann law**: $q = \sigma AT^4$. The constant σ is known as the Stefan-Boltzmann constant and has the value 0.173×10^{-8} Btu/(sq ft)(hr)(deg R)^4 or 5.71×10^{-5} ergs/(sq cm)(sec)(deg K)^4.

The ratio of the total radiating power of a non-black surface to that of a black surface at the same temperature is called the **emissivity** of the surface and is designated by ϵ. More properly, the term is **total hemispherical emissivity** to differentiate it from (1) monochromatic emissivity ϵ_λ, the ratio of radiating powers at the wave length λ, and from (2) directional emissivity ϵ_θ, the ratio of radiating powers in a direction making the angle θ with the normal to the surface. The emissivity of a surface varies with its temperature, its degree of roughness, and, if a metal, its degree of oxidation. Table 1 gives the emissivities of various surfaces and emphasizes the large variation possible in a single material. Although the values in the table apply strictly to normal radiation from the surface (with a few exceptions), they may be used with negligible error for hemispherical emissivity except in the case of polished metal surfaces, for which the hemispherical emissivity is 15 to 20 percent higher than the normal emissivity.

The **absorptivity** α of a surface—the fraction of the impinging radiation which is directly absorbed—depends on the same factors that affect emissivity and, in addition, on the quality of the incident radiation (completely measured by the temperature of the radiator if the latter is black). One may assign two subscripts to α, the first to indicate the temperature of the receiver and the second that of the incident radiation. In general, α_{12} varies more with T_2 than with T_1. **Kirchhoff's law** states that the emissivity of a surface at temperature T_1 is equal to the absorptivity α_{11} which the surface exhibits for radiation from a source at the same temperature; *i.e.*, a surface of relatively low radiating power is also a poor absorber (or good reflector) of radiation from a source at its own temperature.

For vertical tubes,

$$h_m N/k = 0.94(N^3\rho^2\lambda g_L/k\mu_f\Delta)^{0.25} = 0.93(N^3\rho^2 g_L/\mu_f\Gamma)^{1/3} \qquad (13a)$$

The equations show that a tube of given dimensions, for the usual case where N/Dn is greater than 2.76, is more effective in a horizontal than in a vertical position. Thus for $N/Dn = 100$, a horizontal tube gives an average h which is 2.5 times that for a vertical tube. Since there is but little variation in the thermal conductivity or viscosity of the condensate at the condensing temperature at 1 atm, there is little variation in h_m. Thus with horizontal tubes, h_m may be taken as 200 to 400 for the following vapors condensing at atmospheric pressure: benzene, carbon tetrachloride, dichlormethane, dichlordifluoromethane, diphenyl, ethyl alcohol, heptane, hexane, methyl alcohol, octane, toluene, and xylene. Ammonia gives h_m of 1000, and mixtures of steam and organic vapors, forming immiscible condensates, give h_m ranging from 250 to 750, increasing with increasing proportion of steam. With film-type condensation of clean steam on horizontal tubes, h_m ranges from 1000 to 3000, see Eq. (13). With vertical tubes 10 to 20 ft long ripples form in the film; values of h_m from Eq. (13a) should be increased 20 percent.

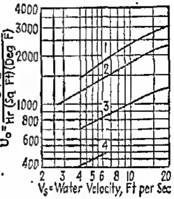

FIG. 4.—Over-all Coefficients between Condensing Steam and Water.

Curve 1. Chrome-plated copper, oleic acid.
Curve 2. Copper, benzyl mercaptan.
Curve 3. Copper, oleic acid.
Curve 4. Admiralty metal, no promoter.

For long vertical tubes, $4\Gamma/\mu$ may exceed 2100; in that case, the value of h_m for $4\Gamma/\mu = 2100$ is conservative. The presence of non-condensible gas, such as air, seriously reduces h, and consequently all vapor-heated apparatus should be well-vented.

With steam, small traces of certain promoters (Nagle, U. S. Patent 1995361) such as oleic acid and benzyl mercaptan become adsorbed in a very thin layer on the surface of the tubes, preventing the condensate from wetting the metal and inducing dropwise condensation, which gives much higher values of h (7000 to 14,000) than film-type condensation. However, with dirty or corroded surfaces, it is difficult to maintain dropwise condensation. Figure 4 shows over-all coefficients U_o for condensing steam at 1 atm on a vertical 10 ft length of copper tube, 5/8 in. O.D., 0.049 in. wall, at various water velocities.

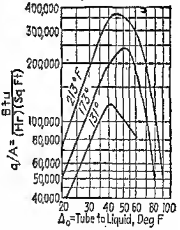

FIG. 5.—Heat Transfer to Boiling Liquid. (Distilled Water on Nickel-plated Copper.)

Boiling Liquids. In natural-convection evaporators, the heat is often supplied by submerged tubes, usually heated internally by condensing vapor. As the temperature difference between tube and liquid is increased, the rate of heat flux q/A increases, owing to better agitation due to more rapid boiling, goes through a maximum at a "critical" temperature difference (Fig. 5); and then decreases rapidly owing to a vapor film of low

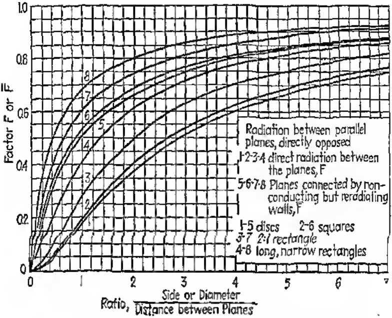

FIG. 1.—Values of the Factor F or $\bar{F}$.

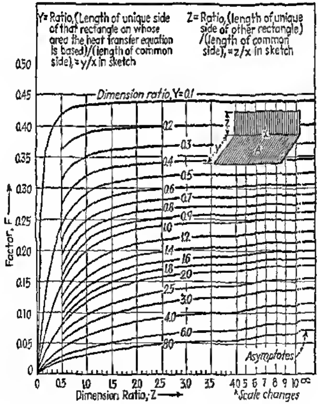

FIG. 2.—Values of the Factor F.

approaching the values obtained in superheating vapor, see Eq. (6a). For comparison, in a natural convection evaporator, a maximum flux of 73,000 Btu per hr per sq ft was obtained at Δ_o of 100 F.

Combined Convection and Radiation Coefficients. In some cases of heat loss, such as that from bare and insulated pipes, where loss is by convection to the air and radiation to the walls of the enclosing space, it is convenient to use a combined convection and radiation coefficient $(h_c + h_r)$. The rate of heat loss thus becomes

$$q = (h_c + h_r)A\Delta_s \qquad (14)$$

where Δ_s is the temperature difference, deg F, between the surface of the hot body and the walls of the space. In evaluating $(h_c + h_r)$, h_c should be calculated by the appropriate convection formula [see Eqs. (11a) to (11e)] and h_r from the equation

$$h_r = 0.692\epsilon(T_{av}/100)^3$$

where ϵ is the black body coefficient of the radiating surface, p. 400, T_{av} is the average temperature of the surface and the enclosing walls, deg R. For oxidized bare steel pipe, the sum $h_c + h_r$ may be taken directly from Table 11.

Table 11. Values of $(h_c + h_r)$
(For horizontal bare or insulated standard steel pipe of various sizes in a room at 80 F)

The combined coefficient $(h_c + h_r)$ for still air in contact with various materials, according to tests conducted by Lichty, University of Illinois, 1915, has the following values:

Cement plaster finish, 0.9; concrete or corkboard, 1.3; brickwork, sheet asbestos, or wood (finished surface), 1.4; glass window or magnesia board, 1.5.

The combined coefficient $(h_c + h_r)$ for the external surface is obtained by multiplying the coefficient for still air by a factor depending on the air velocity.

Velocity, mph	5	10	15	20
Factor for brickwork	2.4	3	3.8	4.2
Factor for wood	2.2	2	2.9	3.0

Harding and Willard ("Mechanical Equipment of Buildings," vol. 1, p. 56) recommend the approximation that the value of $(h_c + h_r)$ for the outside wall surface be taken as 3 times the value for the inside wall surface.

Loss of heat from the surface of a rotating cylinder to air, as in flywheels, armatures, etc., according to the experiments of Hinlein.

Smooth surfaces (polished copper).

Velocity V, fps	0	20	40	60	80	100
Combined coefficient $(h_c + h_r)$	0.47	1.97	2.79	3.14	3.30	3.38

Rough surfaces (dull black, varnished).

$V =$	0	20	40	60	80	100
$(h_c + h_r) =$	0.47	2.49	3.32	3.95	4.50	5.10

The factor $\bar{F}$ is known exactly for a few geometrically simple cases, and may be approximated for others. If A_1 and A_2 are equal parallel disks, squares, or rectangles, connected by non-conducting but reradiating refractory walls, then $\bar{F}$ is given by Fig. 1, lines 5 to 8. If A_1 represents an infinite plane and A_2 is one or two rows of infinite parallel tubes in a parallel plane, and if the only other surface is a refractory surface behind the tubes, $\bar{F}_{12}$ is given by line 5 or 6 of Fig. 3. If an enclosure may be divided into several radiant-heat sources or sinks A_1, A_2, etc., and the rest of the enclosure (reradiating refractory surface) may be lumped together as A_R at a uniform temperature T_R, then the factor $\bar{F}_{12}$ is given in terms of the simpler geometrical factors F by the expression

$$\bar{F}_{12} = F_{12} + \frac{F_{1R}F_{R2}}{(1 - F_{RR})} \tag{4}$$

If this case is further simplified by considering that the only non-refractory surfaces present in the system are heat source A_1 and heat sink A_2 and that each of these can "see" none of itself (i.e., has no negative curvature), the foregoing expression reduces to

$$\bar{F}_{12} = (A_2 - A_1F_{12}^2)/(A_1 + A_2 - 2A_1F_{12}) \tag{5}$$

which necessitates the evaluation of but one geometrical factor F. This case covers a major fraction of problems of radiant-heat interchange between source and sink in a furnace enclosure, and is in error only to the extent to which the assumption of uniform refractory temperature is not permissible. More complicated expressions are available, permitting approach to the exact answer to any desired degree of accuracy depending on the number of zones into which the refractory is divided.

It is sometimes desirable to find the equilibrium value of refractory surface temperature. For the conditions for which Eq. (5) is valid, the refractory surface temperature is given by

$$T_R = \sqrt[4]{\frac{(A_1 - A_1F_{12})T_1^4 + (A_2 - A_1F_{12})T_2^4}{(A_1 - A_1F_{12}) + (A_2 - A_1F_{12})}}$$

Allowance for Non-black Surfaces. The Factor $\mathfrak{F}$. Precise allowance for the departure of surfaces from black or ideal radiating characteristics is in general too complicated for engineering use. However, if the assumption that all surfaces are gray is permitted, a simple and adequate treatment is possible. If nomenclature is as for $\bar{F}$, except that A_1, A_2, etc., are now surfaces having emissivities (and absorptivities) ϵ_1, ϵ_2, etc., it is found that the net radiant interchange between A_1 and A_2, due now to the combined mechanisms of direct radiation, reradiation from refractory surfaces, and multiple reflection inside the enclosure, may be expressed in the form

$$q_{1\rightleftarrows 2} = A_1\mathfrak{F}_{12}\sigma(T_1^4 - T_2^4) = A_2\mathfrak{F}_{21}\sigma(T_1^4 - T_2^4) \tag{6}$$

Just as the factor $\bar{F}$ could be evaluated from F, so the factor $\mathfrak{F}$ can be evaluated from $\bar{F}$. For the case of two non-refractory surfaces A_1 and A_2 and any number of refractory zones,

$$\mathfrak{F}_{12} = 1/[(1/\bar{F}_{12}) + (1/\epsilon_1 - 1) + (A_1/A_2)(1/\epsilon_2 - 1)] \tag{7}$$

It is to be noted that the emissivity of the refractory surfaces forming the system is not a factor, *i.e.*, that whether a refractory surface maintains its equilibrium by complete absorption and black-body reradiation or by complete reflection and no radiation is immaterial.

as 2 as an approximation, since a substantial error in $h_c + h_r$ will have but little effect on the over-all loss of heat. Figure 6 shows the variation in U_o with pipe size and thickness of insulation for 85 percent magnesia for pipe and air temperatures of 375 and 75 F, respectively.

Economical Thickness of Insulation (McMillan, *Trans. A.S.M.E.*, 1926, and *Mech. Eng.*, May, 1929). When it has been determined that the physical properties of a given insulating material are suited to the requirements, the thickness of material for most economical results on flat surfaces is given by the equation $x = \sqrt{12ak/b} - 12Rk$, in which x is the most economical thickness, in., k is the conductivity, b is the cost of insulation per sq ft per in. thickness per year (first cost per sq ft per in. thickness $\times$ fractional annual fixed charges), R is the sum of the resistances of all other elements in the construction, including surface resistance, and $a = Y(t_i - t_a)M/1{,}000{,}000$, in which Y is hours operation per year, t_i is inside temperature, t_a is temperature of surrounding air, and M is the value of heat in dollars per 1,000,000 Btu. For cylindrical surfaces, Fig. 7 may be used; it is based on $12Rk = 0.3$.

These equations and the chart apply to all materials whose cost is proportional to the product of external area times thickness. They may be used for materials whose cost is figured per "board foot." They apply to cork board and to almost all other insulating materials but not to cork pipe covering.

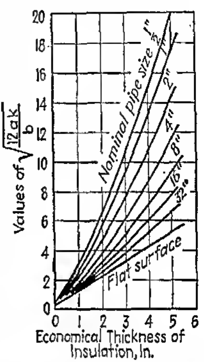

FIG. 7.—Economical Thickness of Insulation on Flat and Cylindrical Surfaces.

Example. If $t_i = 530$, $t_a = 80$, value of heat is \$0.40 per 1,000,000 Btu, hours of operation per year = 7,200, $k = 0.046$, surface resistance = 0.5, cost of insulation = \$0.15 per sq ft per 1 in. thick, and annual fixed charges = 20 percent, then, $a = 7{,}200\ (530 - 80)0.40/1{,}000{,}000 = 1.296$, and $b = 0.15 \times 0.20 = 0.03$.

The economical thickness in flat surface $= \sqrt{1.296 \times 12(0.046)/0.03} - 0.5 \times 12(0.046) = 4.88 - 0.28 = 4.6$ in. (say $4\frac{1}{2}$ in.). The economical thickness for 2 in. pipe (Fig. 7) is 2.1 in. (say 2 in.).

Transmission in Condensers. A valuable graphical method of interpreting the results of tests on surface condensers, proposed by E. E. Wilson, consists in plotting $1/U_o$ as ordinates vs. $1/V_s^{0.8}$, and drawing the best straight line. The value of $1/U_o$, for $1/V_s^{0.8}$ = zero, represents the sum of the resistances of the vapor side R_v, tube wall R_t, and scale deposit R_s. The reciprocal of the slope is the value of B in the expression for the over-all resistance. B is the water-side coefficient at a velocity of 1 fps.

$$1/U_o = R_v + R_t + R_s + 1/BV_s^{0.8}$$

Detailed examples are given in *Trans. A.S.M.E.*, 48, 1926, pp. 1233–1268.

0.208, which means that the net radiation from a tube to the stock is 20.8 percent a much as if the tube were black and completely surrounded by black stock.

Radiation from Flames and Gases

The radiation from a flame is due to radiation from burning soot particle of microscopic and submicroscopic dimensions, from suspended larger pa ticles of coal or ash or both, and from the hot gaseous combustion product

The first of these, soot luminosity, is important where combustion occur under such conditions that hydrocarbon gases in the flame are subjected t heat in the absence of sufficient air, producing thermal decompositio There is at present no method of predicting the luminosity of a flame analyt ically; reliance must be put on experimental measurement of flames simila to that of interest. It is to be noted that visual observation is a poor basi of judgment; a flame so bright that nothing on the other side of it can be see may nevertheless be far from a black body in its radiating characteristic Radiation from such a flame may be estimated from measurements, with a two-color optical pyrometer, of the red and green brightness temperatures of the flame (*Ind. Eng. Chem., Anal. Ed.*, 4, 1932, p. 166).

Radiation from a cloud of microscopic particles (such as a pulverized coal flame) may be calculated if the size, concentration, and temperature of the particles are known, but such an analysis involves so many questionable assumptions as to make the result of limited value.

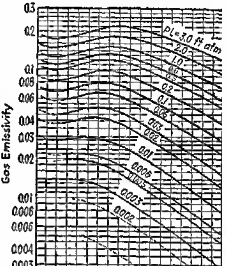

FIG. 5.—Emissivity of Carbon Dioxide.

Of greatest importance in radiant-heat transmission from flames is the infrared radiation from the combustion products, water vapor and carbon dioxide, which overshadows convection at furnace temperatures. If black-body radiation passes through either of these gases, absorption occurs at certain wave lengths. Con versely, if these gases are heated, they emit radiation at those same wav lengths. Consider a hemispherical gas mass of radius L containing carbo dioxide of partial pressure P_c, and let the problem be the evaluation of radiant heat interchange between the gas at temperature T_G and a small element o surface at temperature T_S, located on the base of the hemisphere at its center Per unit of surface, the emission of the gas to the surface is $\sigma T^4{}_G \cdot \epsilon_G$ where ϵ denotes gas emissivity. For carbon dioxide, ϵ_G depends on T_G, the total pres sure, and the product term P_cL, and is given in Fig. 5 which applies for the usua case of total pressure constant at 1 atm. The absorption, by the gas, of radia tion from the surface is $\sigma T^4{}_S \cdot \alpha_G$ where α_G is the absorptivity of the gas fo black-body radiation from the surface. Approximately, α_G is obtained fron the gas-emissivity chart at the same value of P_cL as before but at the tempera ture T_S instead of T_G. Such an approximation is adequate if the gas is hotte

Table 1. Emissivity of Surfaces

Surface	Temp,[a] deg F	Emissivity[a]
METALS AND THEIR OXIDES

[a] When two temperatures and two emissivities are given they correspond, first to first and second to second, and linear interpolation is permissible.

absorptivities from Figs. 5 and 6. As PL approaches zero, the mean beam length approaches, as a limit, the value, 4 × (ratio of gas volume to bounding area). For the range of PL encountered in practice, L is always less; 85 percent of the limiting value is generally a satisfactory approximation (F. J. Port, M.I.T. D.Sc. Thesis, 1939). Table 2 summarizes the recommendations.

If gas radiation occurs in a space in which there is a continuous change in temperature of the gas and the surface from one end to the other of the interchanger, exact allowance can be made by conventional graphical integration. A fair approximation may be obtained by using a mean surface temperature equal to the arithmetic mean, and a mean gas temperature equal to the mean surface temperature plus the logarithmic mean of the temperature difference, gas to surface, at the two ends.

$$t_{S_{\text{avg}}} = (t_{S_1} + t_{S_2})/2$$

$$t_{G_{\text{avg}}} = t_{S_{\text{avg}}} + \frac{(t_{G_1} - t_{S_1}) - (t_{G_2} - t_{S_2})}{2.3 \log [(t_{G_1} - t_{S_1})/(t_{G_2} - t_{S_2})]}$$

Table 2. Beam Lengths for Gas Radiation

Shape	Characterizing dimension, D	Factor by which D is multiplied to obtain mean beam length, L	
		When $PL = 0$	For average values of PL
Sphere	Diameter	$\frac{2}{3}$	0.60
Infinite cylinder	Diameter	1	0.90
Space between infinite parallel planes	Distance between planes	2	1.8
Cube	Edge	$\frac{2}{3}$	0.60
1 × 2 × 6 rectangular parallelepiped, radiating to	Shortest edge		
2 × 6 face	....	1.16	1.06
1 × 6 face	....	1.24	
1 × 2 face	....	1.18	
All faces	....	1.20	
Space outside infinite bank of tubes with centers on equilateral triangles; tube diameter = clearance	Clearance	3.4	2.8
Same as preceding, except tube diameter = one-half clearance	Clearance	4.45	3.8

Example. Flue gas containing 9.5 percent CO_2 and 7.1 percent H_2O, wet basis, flows through a bank of tubes of 1.5 in. on equilateral triangular centers 4.5 in. apart. In a section in which the gas temperature drops from 1900 to 1515 F while the tube surface changes from 1050 to 950 F, what is the heat-transfer rate per square foot of tube area, due to gas radiation only? Tube surface emissivity = 0.8.

$$t_{S_{\text{avg}}} = (1050 + 950)/2 = 1000 \text{ F}$$

$$t_{G_{\text{avg}}} = 1000 + \frac{(1900 - 1050) - (1515 - 950)}{2.3 \log (850/565)} = 1700 \text{ F}$$

$$P_cL = 0.095(3.8 \times 4.5/12) = 0.135 \text{ ft atm}$$

$$P_c'L = 0.135(1460/2160) = 0.091 \text{ ft atm at } 1000 \text{ F}$$

$$P_wL = 0.071(3.8 \times 4.5/12) = 0.102 \text{ ft atm}$$

From Fig. 5, for CO_2:

$$\epsilon_G \text{ (at } t_G = 1700, P_cL = 0.135) = 0.080$$

$$\alpha_G \text{ (at } t_S = 1000, P_c'L = 0.091) = 0.075 \times (2160/1460)^{0.65}$$

The net loss of energy by radiation from a body at temperature T_1 in black surroundings at T_2 is given by

$$q_{1,\text{net}} = 0.173A_1[\epsilon_1(T_1/100)^4 - \alpha_{12}(T_2/100)^4] \quad (1)$$

where the units are Btu, ft, hr, deg R.

If the temperatures are so close together that $\alpha_{12} = \alpha_{11} = \epsilon_1$, or if A_1 is a gray surface (monochromatic emissivity the same at all wave lengths), the preceding relation simplifies to

$$q_{1,\text{net}} = 0.173A_1\epsilon_1[(T_1/100)^4 - (T_2/100)^4] \quad (2)$$

The more complicated but important case of radiation interchange in a system of several surfaces at different temperatures and emissivities involves evaluation of a geometrical factor F. F_{12} is defined as the fraction of the radiation leaving surface A_1 in all directions which is intercepted by surface A_2. Values of F have been calculated for various surface arrangements on the assumption that emissivity ϵ_θ is constant, independent of θ. This is exact for black surfaces and quite good for most non-metallic, tarnished, or rough metal surfaces. Values of F for opposed parallel rectangles and disks of equal size appear as lines 1 to 4 of Fig. 1, for perpendicular adjacent rectangles in Fig. 2, for an infinite plane parallel to a system of rows of parallel tubes as lines 1 and 3 of Fig. 3. Other cases are treated in the literature (*Mech. Eng.*, 52, 1932, p. 699). Important and useful concepts in evaluating F's are that $A_1F_{12} = A_2F_{21}$ (since otherwise there would be a net heat flux between A_1 and A_2 even when at the same temperature); that $F_{11} + F_{12} + F_{13} + \cdots = 1$; that of course $F_{11} = 0$ when A_1 can "see" no part of itself.

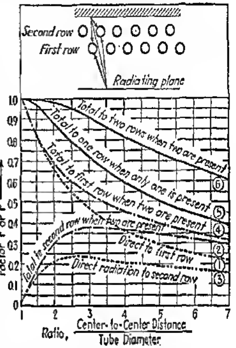

FIG. 3.—Values of F or $\bar{F}$.

In an enclosure of black surfaces, the net heat flux from A_1 is then given by

$$\begin{aligned} q_{1,\text{net}} &= (A_1F_{12}\sigma T_1^4 - A_2F_{21}\sigma T_2^4) + (A_1F_{13}\sigma T_1^4 - A_3F_{31}\sigma T_3^4) + \cdots \\ &\equiv A_1F_{12}\sigma(T_1^4 - T_2^4) + A_1F_{13}\sigma(T_1^4 - T_3^4) + \cdots \\ &\equiv A_1\sigma T_1^4 - (A_1F_{11}\sigma T_1^4 + A_2F_{21}\sigma T_2^4 + A_3F_{31}\sigma T_3^4 + \cdots) \end{aligned} \quad (3)$$

Allowance for Refractory Surfaces. The Factor $\bar{F}$. Consider an enclosure consisting in part of black heat sources and sinks A_1, A_2, A_3 . . . and in part of refractory surfaces A_R, A_S . . . from which there is no *net* radiant-heat flux (fulfilled by the average refractory wall where difference between internal convection and external loss is minute compared with incident radiation). The unknown refractory surface temperatures may be eliminated by heat balances, yielding an equation that expresses the net flux $q_{1\rightleftharpoons2}$ from A_1 to A_2 by the combined mechanisms of direct radiation plus reradiation from the refractory surfaces:

$$q_{1\rightleftharpoons2} = A_1\bar{F}_{12}\sigma(T_1^4 - T_2^4) \equiv A_2\bar{F}_{21}\sigma(T_1^4 - T_2^4)$$

$$q_F = \sigma(T^4_F - T^4_C)A_C\left[\frac{1}{\frac{1}{\epsilon_C} + \frac{A_C}{A_C + A_R}\left(\frac{1}{\epsilon_F} - 1\right)}\right] + h_C A'_C(T_F - T_C) + U_R A_R(T_F - T_O) \quad (12)$$

From this simplified form it may be seen that increasing the flame emissivity increases the heat transmission, but not proportionately; that decreasing surface emissivity (and absorptivity) from unity when the flame is very transparent produces almost no effect on the heat transmission; but that decreasing ϵ_C from unity when the flame is substantially opaque ($\epsilon_F = 1$) produces a proportional decrease in heat transmission.

The derivation of Eqs. (9) and (12) was based on the assumption that A_C was composed of plane areas. If, instead, it is a row of tubes mounted in front of a refractory wall, the value of A_C in the radiation term of the preceding equations is the continuous plane A_p in which the tubes are located, multiplied by the proper factor $\bar{F}$ for tubes with a refractory background (see Fig. 3); the refractory surface A_R should be increased by the amount $(1 - \bar{F})A_p$.

Equations (9) and (12) express a relation between two unknowns T_F and q_F, and a second relation is necessary if a solution is to be obtained. The other relation is an energy balance. If one assumes turbulence to be so great that the mean flame temperature T_F used for calculation of radiation is the same as the temperature T_G of the gas leaving the chamber, then

$$q_F = H - N(T_F - T_O) \quad (13)$$

where H represents the enthalpy or heat content of the entering fuel, air, and recirculated flue gas if any, above a base temperature T_O (water as vapor); and N represents the hourly mean heat capacity (evaluated between T_F and T_O) of the gas leaving the chamber. Equations (9) [or (12)] and (13) may be solved by trial-and-error or by graphical methods involving superimposed plots. Better agreement between predicted and experimental results is obtained on some furnaces when the assumption is made that flame temperature and exit gas temperature are not the same, but differ by a constant amount. In a number of furnace tests, the difference was about 300 F.

Simplified Treatment of Combustion-chamber Heat Transmission. Equation (9) or its equivalent has been used as a basis for deriving various simplified relations, easier to use but restricted in applicability in proportion to the degree of simplification. Several of these follow.

Billet-reheating Furnaces. For continuous billet-reheating furnaces, Eq. (9) may be modified as follows: (1) q is heat transferred to the stock, not from the flame; (2) convection terms have been omitted; (3) to compensate therefor and to allow for steadiness of furnace operation, $\mathfrak{F}_{CF}$ is evaluated using $1.2f \cdot \epsilon_F$ instead of ϵ_F, where f is the ratio of average billet-pushing rate over a period of several hours to pushing rate during periods of steady operation; (4) ϵ_F is flame emissivity due to CO_2 and H_2O only, as calculated in the previous example on gas radiation; (5) $F_{RC} = A_C F_{CR}/A_R = A_C/A_R$; (6) an average value of $(T^4_F - T^4_C)$ is used, equal to the geometric mean of its value at the two ends of the furnace; and at the hot end T_F is taken as the calculated "theoretical" flame temperature, or adiabatic combustion temperature. The equation has been tested on reheating furnaces of various types and found satisfactory (*A.S.M.E.*, **58**, 1936, p. 185; *Heat Treating Forging*, **22**, 1936, pp. 144–149, 193–198).

Petroleum Heaters. For cracking-coil and tube-still furnaces, Eq. (9) may be modified as follows: (1) by omitting the last term, q becomes heat

As in the case of $\bar{F}$, $\mathfrak{F}$ may be evaluated to any desired degree of accuracy by dividing the system into a sufficient number of zones; but most furnace problems do not justify going beyond the expression given above.

Example. A furnace chamber of rectangular parallelopipedal form is heated by the combustion of gas inside vertical radiant tubes lining the side walls. The tubes are 5 in. O.D., on 12 in. centers. The stock forms a continuous plane on the hearth. Roof and end walls are refractory. Dimensions are shown in Fig. 4. The radiant tubes and stock are "gray" bodies having emissivities 0.8 and 0.9, respectively. What is the net rate of heat transmission to the stock by radiation when the mean temperature of the tube surface is 1500 F and that of the stock is 1200 F?

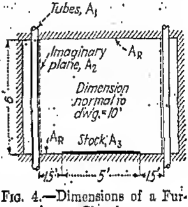

FIG. 4.—Dimensions of a Furnace Chamber.

This problem must be broken up into two parts, first considering the walls with their refractory-backed tubes. To imaginary planes A_2 of area 6×10 ft and located parallel to and inside the rows of radiant tubes, the tubes emit radiation $\sigma T_1^4 A_1 \mathfrak{F}_{12}$, which equals $\sigma T_1^4 A_2 \mathfrak{F}_{21}$. To find $\mathfrak{F}_{21}$ use Fig. 3, line 5, from which $\bar{F}_{21} = 0.81$. Then from Eq. (7),

$$\mathfrak{F}_{21} = 1/[(1/0.81) + (1/1 - 1) + (12/5\pi)(1/0.8 - 1)] = 0.702$$

This amounts to saying that the system of refractory-backed tubes is equal in radiating power to a continuous plane A_2 replacing the tubes and refractory back of them, having a temperature equal to that of the tubes and an equivalent or effective emissivity of 0.702.

The new simplified furnace now consists of an enclosure formed by two 6×10 ft radiating side walls (area A_2, of emissivity 0.702), a 5×10 ft receiving plane on the floor (A_3), and refractory surfaces (A_R) to complete the enclosure (ends, roof, and floor side strips); the desired heat transfer is $q_{2\rightleftarrows 3}$.

$$q_{2\rightleftarrows 3} = \sigma(T_1^4 - T_3^4)A_2\mathfrak{F}_{23}$$

To evaluate $\mathfrak{F}_{23}$, start with the direct interchange factor F_{23}. $F_{23} = F$ from (A_2) to $(A_3 +$ a strip of A_R alongside A_3 which has a common edge with $A_2)$ minus F from (A_2) to (the strip only). These two F's may be evaluated from Fig. 2. For the first F, $Y = 8/10$, $Z = 6.5/10$, $F = 0.239$; for the second F, $Y = 8/10$, $Z = 1.5/10$, $F = 0.100$. Then $F_{23} = 0.239 - 0.10 = 0.139$. Now $\bar{F}$ may be evaluated.

$$\bar{F}_{23} = F_{23} + \frac{1}{(1/F_{2R}) + (A_2/A_3)(1/F_{3R})}$$

Since A_2 "sees" A_R, A_3, and some of itself (the plane opposite), $F_{2R} \doteq 1 - F_{22} - F_{23}$. F_{22}, the direct interchange factor between parallel 6×10 ft rectangles separated by 8 ft, may be taken as the geometric mean of the factors for 6 ft squares separated by 8 ft, and 10 ft squares separated by 8 ft. These come from Fig. 1, line 2, according to which $F_{22} \doteq \sqrt{0.13 \times 0.255} = 0.182$. Then $F_{2R} = 1 - 0.182 - 0.139 = 0.679$. The other required direct factor is $F_{3R} = 1 - F_{32} = 1 - F_{23}A_2/A_3 = 1 - 0.139 \times 120/50 = 0.666$. Then $\bar{F}_{23} = 0.139 + \dfrac{1}{(1/0.679) + 120/50)\,(1/0.666)} = 0.336$. Having $\bar{F}_{23}$, we may now evaluate the factor $\mathfrak{F}_{23}$.

$$\mathfrak{F}_{23} = \frac{1}{(1/0.336) + [(1/0.702) - 1] + (120/50)[(1/0.9) - 1]} = 0.273$$

$$q_{net} = \sigma(T_1^4 - T_3^4)A_2\mathfrak{F}_{23} = 0.173(19.6^4 - 16.6^4)(120)(0.273)$$
$$= 408{,}000 \text{ Btu per hr}$$

A result of interest is obtained by dividing the term $A_2\mathfrak{F}_{23}$ (120×0.273, or 32.7) by the actual area A_1 of the radiating tubes $\left(\frac{5\pi}{12} \times 60 \times 2 = 157 \text{ sq ft}\right)$. This is $32.7/157 =$

than the surface and the absorption term consequently of secondary importance. If the reverse is the case, an accurate value of α_G may be obtained if one reads an emissivity from Fig. 5 at T_S as before but at $PL(T_S/T_G)$ instead of PL and then multiplies the result by $(T_G/T_S)^{0.65}$.

The net radiant-heat interchange is then

$$(\sigma T^4{}_G\, \epsilon_G - \sigma T^4{}_S \,.\, \alpha_G)\epsilon_s$$

where the term ϵ_s allows for the non-black character of the surface.

For water vapor, the gas emissivity ϵ_G is similarly determined by T_G and the product P_wL, and is given in Fig. 6. The absorptivity is given with adequate accuracy by use of a gas emissivity corresponding to P_wL and T_S. There is good evidence (*Ver. deut. Ing. Forschungsheft* 387) that for water vapor, in contrast to carbon dioxide, P_w and L enter as separate variables and not as a single product. However, unpublished experimental data believed to be of high accuracy are in much better agreement with predictions from the charts given here than with those in which allowance is made for the effect of partial pressure P_w in addition to P_wL. Consequently, the simpler procedure is recommended until more data are obtained. The present water-vapor chart is probably conservative at low L's and high P_w's.

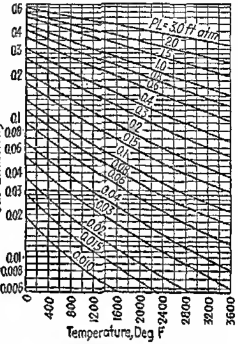

FIG. 6.—Emissivity of Water Vapor.

When carbon dioxide and water vapor are present together, the total radiation due to both is somewhat less than the sum of the separately calculated effects because each gas is somewhat opaque to radiation from the other. A rough but adequate correction for this effect may be read from Fig. 7 in the form of a correction factor K by which the total radiation is reduced. The final formulation of interchange between a gas and its bounding surface is then

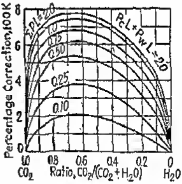

FIG. 7.—Values of Correction Factor, K.

$$q/A = \epsilon_s[\sigma T^4{}_G(\epsilon_{G,CO_2} + \epsilon_{G,H_2O}) - \sigma T^4{}_S(\alpha_{G,CO_2} + \alpha_{G,H_2O})](1 - K) \quad (8)$$

The preceding expression was formulated for the case of interchange between a gas hemisphere and a spot on its base, *i.e.*, for the case in which the length of path L of the radiant beam is the same in all directions. For gas shapes of industrial importance, it is found that any shape is approximately representable by an "equivalent" hemisphere of proper radius, or that there is a mean beam length which can be used in evaluating gas emissivities and

MECHANICAL PROPERTIES OF MATERIALS

Failure of a material or of a structural part may occur by **fracture** (such as the shattering of glass), **yielding**, **wear**, **corrosion**, and other causes. These failures are failures of the material. **Buckling** may cause failure of the part without any failure of the material.

As load is applied, **deformation** takes place before any final fracture occurs. With all solid materials, some deformation may be sustained without permanent deformation, *i.e.*, the material behaves **elastically**. Beyond the **elastic limit**, the elastic deformation is accompanied by varying amounts of **plastic**, or permanent, deformation. If a material sustains large amounts of plastic deformation before final fracture, it is classed as a **ductile** material, and if fracture occurs with little or no plastic deformation, the material is classed as **brittle**.

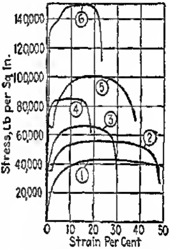

FIG. 1.—Comparative Stress-strain Diagrams. (1) Soft Brass. (2) Low-carbon Steel. (3) Hard Bronze. (4) Cold-rolled Steel. (5) Medium-carbon Steel, Annealed. (6) Medium-carbon Steel, Heat-treated.

Stress-strain Diagrams. Tests of materials may be made in many different ways, such as torsion, compression, and shear, according to the service to which the materials are to be put, but the tension test is the most common and is qualitatively characteristic of all the other types of tests except those made under extremely high hydrostatic pressure. The action of a material under the gradually increasing extension of the tension test is usually represented by plotting **apparent stress** (the total load divided by the original cross-sectional area of the test piece) as ordinates against the **apparent strain** (elongation between two gage points marked on the test piece divided by the original gage length) as abscissas. Typical curves for metals are shown in Figs. 1, 2, and 3. In these, the elastic deformation is, approximately, a straight line, as called for by **Hooke's law**, and the slope of this line, or the ratio of stress to strain within the elastic range, is the **modulus of elasticity** E, sometimes called **Young's modulus**. Beyond the elastic limit, permanent or plastic strain occurs (Fig. 3). If the stress

From Fig. 6, for H_2O:

$$\epsilon_G \text{ (at } t_G = 1700, P_wL = 0.102) = 0.048$$
$$\alpha_G \text{ (at } t_G = 1000, P_wL = 0.102) = 0.072$$

From Fig. 7, the correction due to superimposed radiation is 3.5 percent. Then substituting in Eq. (8):

$$q/A = 0.8[0.173 \times 21.6^4(0.080 + 0.048) - 0.173 \times 14.6^4(0.097 + 0.072)](1 - 0.035) = 2700 \text{ Btu per sq ft per hr,}$$

equivalent to a convection coefficient of 2700/700, or 3.8.

One may define the over-all emissivity ϵ_F of an equivalent "gray" flame by the relation

$$q/A = 0.8\sigma(21.6^4 - 14.6^4)\epsilon_F = 23{,}700\epsilon_F$$

from which ϵ_F is 2700/23,700, or 0.113.

Heat Transmission in the Combustion Chamber of a Furnace

The so-called radiant section of a furnace presents a heat-transfer problem in which there enters the combined action of direct radiation from the flame to the stock or heat sink, radiation from flame to refractory surfaces thence back through the flame (with partial absorption) to the sink, convection, and external losses. A solution of the problem is possible if the following assumptions are accepted: (1) external losses from refractory walls equal convection from flame to refractory; (2) the flame is gray and has an emissivity ϵ_F (defined as in the previous example, with suitable additions for soot luminosity, etc.); (3) all refractory surfaces have a common average (but unknown) temperature; (4) a mean temperature T_F is assignable to the flame and combustion products in the chamber; (5) the heat sink or ultimate receiver has a uniform surface temperature T_C and is gray, with emissivity ϵ_C and area A_C. The solution of the problem, giving the net rate of heat transfer q_F from the flame by all mechanisms, is

$$q_F = \underbrace{\sigma(T^4_F - T^4_C)A_C\mathfrak{F}_{CF}}_{\text{radiation to sink}} + \underbrace{h_CA'_C(T_F - T_C)}_{\text{convection to sink}} + \underbrace{U_RA_R(T_F - T_O)}_{\text{external loss}} \tag{9}$$

in which

$$\mathfrak{F}_{CF} = \frac{1}{(1/\bar{F}_{CF}) + (1/\epsilon_C) - 1} \tag{10}$$

$$\bar{F}_{CF} = \epsilon_F\left[1 + \frac{A_R/A_C}{1 + \epsilon_F/(1 - \epsilon_F)(1/F_{RC})}\right] \tag{11}$$

$$U_R = \frac{1}{(1/h_R) + (L/k) + (1/h_O)}$$

In these equations h_C, h_R, and h_O represent convection coefficients at the sink, inside refractory, and outside refractory surfaces, respectively; L and k are wall thickness and thermal conductivity of the refractory; T_O is outside air temperature; A'_C differs from A_C in excluding that cold surface or ultimate-receiver area which, though in view of the flame and receiving radiation, does not receive heat by convection from the gases until they leave the chamber.

It is to be noted that, as in the case of radiation in an enclosure containing no radiating or absorbing gas, F is built up from $\bar{F}$ and ϵ_C, and $\bar{F}$ from F; but here the flame emissivity ϵ_F is involved. Some simplification is possible if the geometrical factor F_{RC} (the fraction of the radiation leaving refractory surfaces which is directed towards the "cold" surface or heat sink) is replaced by $A_C/(A_R + A_C)$—a fair approximation when the refractory and cold surfaces are not completely segregated from each other. Then

reached in this region is called the **yield point** (YP) and is of great importance in design as well as one that is easily measured. Because certain factors such as surface finish and speed of loading have been found to influence the yield point, latest practice designates this point as the **upper yield point** and the lower part of the yielding region as the **lower yield point**, the latter being taken as the significant and reproducible value. In the harder and stronger steels, and under certain conditions of temperature, the yielding phenomenon is much less prominent and is correspondingly harder to measure.

In materials that do not exhibit a marked yield point, it is customary to measure a **yield strength**. This is arbitrarily defined as the stress at which the material has a specified permanent set (the value of 0.2 percent is widely accepted) and may be determined by measuring off the required set from the origin of the plot and running a line from the point thus found parallel to the original elastic line. The intersection of this line with the curve will give the required yield strength, as shown in Fig. 3 by the point X. Similar arbitrary rules are followed with regard to the elastic limit in commercial practice. Instead of determining the stress up to which there is no permanent set, as required by definition, it is customary to designate the end of the straight portion of the curve (by definition the **proportional limit**) as the elastic limit. Careful practice qualifies this by designating it the **proportional elastic limit**. Although in most materials elasticity and the linearity of the stress strain are closely associated, there are materials that show a non-linear stress-strain relation and yet behave at least approximately elastically. Among these are cast iron, rubber, and, to a certain extent, concrete. These show increasing deformation rates with increasing stress, but a few composite structures such as rope show the reverse action and stiffen at higher stresses. There are also a number of materials such as moist wood that show almost perfect linearity of stress with respect to strain and yet are decidedly inelastic at all loads.

Work hardening, or cold work, is the plastic deformation of a metal, as in a tensile, compressive, or shear test. Beyond the yield range in steel, or beyond the proportional elastic limit in materials that have no definite yielding, cold work increases the proportional elastic limit and the yield strength (or yield point). A material cold-worked to X in Fig. 3 and then released would show a new proportional elastic limit just below X and a correspondingly higher yield strength if retested starting at X'. If a material that has been thus strengthened in tension by tensile cold work is tested in compression, a much smaller strengthening may be found and in many cases an actual weakening of the compressive proportional elastic limit and yield strength will occur, so that cold working introduces definitely **directional properties**. There is a loss of ductility in cold working which corresponds directly to the amount of plastic deformation used in the working process. Heat-treatment after cold working is often extremely beneficial, particularly in removing the directional effect.

Ductility. The ability of materials to suffer large amounts of plastic deformation without fracture is known as **ductility** if the deformation is tensile and as **malleability** if the deformation is compressive, the two properties being similar but not identical and not present to similar degrees in different materials. Ductility is measured commercially by the **ultimate elongation**, sometimes called the **percent elongation** (expressed as a per-

transferred to oil instead of heat lost by flame; (2) $h_C A_C'$ has for simplification been assigned an average value equal to $7A_C\mathfrak{F}_{CF}$ (the term is unimportant relative to the radiation term). The relation is then

$$q_C = [\sigma(T^4_F - T^4_C) + 7(T_F - T_C)]A_C\mathfrak{F}_{CF} \tag{14}$$

Comments on p. 415 concerning the proper values of A_C and A_R for the case of tubes mounted on a wall apply. In evaluating $\mathfrak{F}_{CF}$, ϵ_F is calculated allowing for gas radiation only; $\epsilon_C = 0.9$. F_{RC} is found to be represented adequately by $A_C/(A_C + A_R)$ for values of A_R/A_C from 0 to 1, by A_C/A_R for values of A_R/A_C from 3 to 6.5. Since Eq. (14) involves heat received by oil rather than heat lost by the flame, when it is combined with the energy balance represented by Eq. (13), the latter must be modified. H is replaced by $H(1 - \beta)$, where βH is the external heat loss from the combustion chamber. A simplified graphical treatment of the solution of Eqs. (14) and (13) is available in the literature (*Am. Inst. Chem. Eng.*, 35, 1939, p. 743), together with a comparison of results with 85 tests on 19 furnaces of widely different types and excess air, burning fuel oil or refinery gas; the average deviation was 5.3 percent; excluding tests almost certainly bad, the average deviation was less than 4 percent.

A relation for petroleum heaters, somewhat simpler and quicker to use than Eq. (14) but not so safe, is obtainable by assuming certain terms in Eq. (9) constant, combining with Eq. (13) to eliminate T_F, and finding an expression different in form but numerically similar over the range of interest. The relation is

$$\mu = 1\Bigg/\left[1 + \sqrt{H/A_C\mathfrak{F}_{CF}}/1.4\left(\frac{H/N}{100}\right)^{1.4}\right] \tag{15}$$

where μ is the ratio of heat transferred to oil to the enthalpy of the entering air and fuel (net value). Other equations applicable in this field are available (*Ind. Eng. Chem.*, 24, 1932, p. 486; *Nat. Petr. News*, July 27, 1938).

Steam-boiler Furnaces. For calculating heat transmission in the radiant sections of steam-boiler furnace settings, many empirical relations are available. One of the simplest is the Orrok-Hudson equation

$$\mu = 1/(1 + (G\sqrt{C_0}/27)) \tag{16}$$

in which G is the weight ratio of air to fuel, C_0 is the firing rate expressed as pounds of equivalent good bituminous coal per hour per square foot of exposed tube area (complete circumference if not buried in wall).

Mullikin (*A.S.M.E.*, 57, 1935, p. 517) assumes that the flame emissivity ϵ_F is unity for large pulverized coal-, oil-, or gas-fired furnaces and that compensation for this high value may be made by using the same value for gas temperature in Eqs. (9) and (13). When ϵ_F is unity, the term $A_C\mathfrak{F}_{CF}$ of Eq. (9) becomes simply $A_C\epsilon_C$ (see p. 415 for the proper evaluation of A_C). Mullikin introduces additional multiplying factors on A_C to allow for resistance of overlying slag or refractory facing on metal-block walls. These are 0.7 for bare-faced metal blocks on tubes, 0.35 for refractory-faced metal blocks on tubes. The simplification suggested is unsafe to use on small furnaces where ϵ_F is certainly not unity.

Wohlenberg (*A.S.M.E.*, 47, 1925, p. 127; 57, 1935, p. 531) uses a relation intrinsically similar to Eq. (12), together with a heat balance involving the assumption of equality of flame and exit gas temperatures; he presents the relation for μ in the form of the product of a number of quantities each making separate allowance for one of the variables under control.

Reduction of area is somewhat related to malleability, but is not a direct measure of that property. With certain of the stronger metals which show a low ultimate elongation, the reduction of area may be an important criterion of the value of the material. Ductility and malleability are of importance both in the cold-working operation in manufacturing and as safety factors when a structural part is subjected to shock loading.

Elasticity. The ability of a material to return to its original dimensions after removal of stresses is known as **elasticity**. In metals, the amount of elastic deformation, or strain, is microscopic in amount, but it controls the distribution of stress in all structural parts within their working loads. In almost all metals, the elastic action is associated with the early straight portion of the stress-strain curve and with the straight lines obtained on release of stresses beyond the proportional elastic limit. The value of the modulus of elasticity E is the same in compression and in tension for most metals, the notable exception being cast iron. In metals that have a very low proportional elastic limit, the determination of E should be made from the slope of a line tangent to the stress-strain curve at zero stress, or equally well from the slope of the lines obtained on release of stresses above the proportional elastic limit, and the value so obtained is known as the **tangent modulus of elasticity**.

Shear. Stress-strain diagrams for shear loading of a material are similar to those for tension and compression, but are difficult to obtain since it is almost impossible to load a test piece in pure shear. Common tests involving shear include the **torsion test**, as a shaft, and the so-called **direct shear test**, as a rivet. Neither of these is a fundamental test, but satisfactory strengths for the design of shafts and rivets may be obtained from them. Ordinarily, only the maximum load is of interest in the rivet test and the

The color, grain, and shear of the fracture are significant. Forms of fracture are shown in Fig. 4. Terms describing fracture are: silky, dull, granular, crystalline, fibrous.

Failure under compression (Fig. 5) depends on material, slenderness of specimen, and restraint at ends or sides. **Short blocks of brittle materials** like cast iron, stone, cement, when unconfined at the sides, fail in compression, by sliding along inclined planes. The angle of these planes is a function of the shearing stress and of the coefficient of friction of the material. Internal cones (with their bases at the pressure heads of the testing machines) and pyramids form in cylindrical and rectangular specimens, respectively.

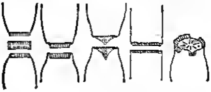

Fig. 4.—Typical Metal Fractures in Tension.

Stress Concentration. In a structural part having any sort of notch or groove, or any abrupt change in cross section, the maximum stress in that region will occur immediately at the notch, groove, or change in section and will be higher than the stress calculated on simple assumptions of stress distribution. The ratio of this maximum stress to the nominal stress (by

Fig. 5.—Typical Compression Fractures.

the simple assumption) is the **stress concentration factor** K for the particular shape and is a constant, independent of the material, except for non-isotropic materials such as wood. One method of determining stress-concentration factors is by the use of photoelasticity, in which transparent models are examined under polarized light, and from this and other sources Figs. 6 to 13 have been compiled. With brittle materials such as glass, this concentration is serious and weakens the piece directly, but with more ductile materials, under ordinary static loading, the material flows sufficiently to eliminate in part or in whole the weakening due to the concentration.

Impact. When a structure is loaded in *impact*, *i.e.*, is struck a blow, the stresses may rise sufficiently high to cause plastic flow. If this flow is distributed through a considerable volume of material, it will not result in fracture unless the blows are continued, and hence it is not harmful unless the exact shape of the part is of importance, as in gear teeth. On the other hand, if a region of stress concentration is present, either in the notch form or in the form of internal weaknesses in the microstructure of the material, then the plastic flow will be correspondingly concentrated and the velocity of flow speeded up, and there may result a brittle type of fracture originating at the concentration and known as **impact failure.** The resistance of different materials to this type of failure is naturally greater with those having ductility than with the brittle materials, but beyond this there is no correlation between **impact strength** and the other properties. Impact tests may be made by measuring the energy required to fracture a standard notched specimen such as the Charpy or Izod (see Fig. 25) either in tension or in bending, but the values so obtained are merely comparative between different materials tested by the same method and cannot be used directly in design. Table 4

is released from point X, the material will contract along XX', generally nearly straight and parallel to the original elastic line, leaving a **permanent set** OX'. The parallelism of these two lines is generally assumed, and the permanent set may be determined by measuring $X''X$ without releasing the load or stopping the test. On reloading from the point X', the line $X'X$ is followed until the original curve is nearly reached at X, where a new elastic limit occurs and the curve then follows a continuation of the original curve just as if the release of stress had not been made. As extension is continued, the material becomes stronger causing a rise of the curve, but at the same time the cross-sectional area of the specimen becomes less as it is drawn out. This loss of area weakens the specimen so that the curve reaches a maximum and then falls off until final fracture occurs (Fig. 1). The stress at the maximum point is called the **tensile strength** (TS) of the material and is its most often quoted property.

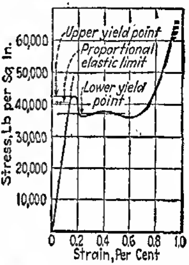

FIG. 2.—Yielding of Annealed Steel.

In a **compression test**, most metals in their annealed condition show a graph which in its early part is exactly the same as for a tension test, but in the part where the change of area exerts a prominent effect the curve rises instead of falling because the area becomes greater. Thus a compression test does not reach a maximum in the same way that a tension test does, and unless shearing, splitting, or crumbling occurs there may not be any fracture and consequently no definite **compressive strength** may be quoted. It is customary to use the tensile strength for the compressive strength when necessary in such cases, although there is little fundamental justification for the practice.

The usual curves for both tension and compression do not give a true picture of the strength of the material itself since they both include the effect of the change of area, *i.e.*, they represent the specimen rather than the material. The **true stress-strain** diagram may be plotted by dividing each load by the actual area of the specimen at the time and by treating strain in a similar manner. When this is done, the compressive and tensile curves become identical for most annealed metals, but little commercial use is made of the true stress-strain relationships except in some of the cold-working operations in manufacturing.

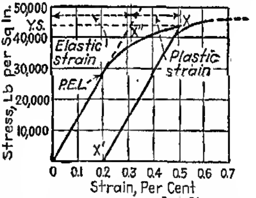

FIG. 3.—General Stress-strain Diagram.

In steels, a curious phenomenon occurs soon after the elastic limit, known as **yielding**. This gives rise to a dip in the general curve (Fig. 2) followed by a period of deformation at approximately constant load before the curve begins to rise again with strengthening of the material. The maximum stress

gives representative impact strengths. The impact strength of a material, as here treated, has to do with highly localized, and generally indeterminate, conditions.

Fatigue

When a body containing a region of stress concentration is loaded, the material may flow locally without failure. If the load is reversed, the plastic flow is likewise reversed, and with many repetitions of this cycle a crack may develop in the flowing material. This crack then tends to progress, or propagate, by the same action that originated it, and eventually the member may fail by **fatigue**. Fatigue cracks originate at obvious surface notches and defects, but they may also start at local weaknesses in the microstructure of the material. Fatigue failure may occur at reversed stresses which are considerably below the elastic limit as determined in an ordinary static test.

In fatigue testing, the common loading is alternate tension and compression, of equal numerical value, obtained by rotating a smooth cylindrical specimen while under bending load and noting the number of cycles required to produce failure. Other specimens of the same material are then tested at higher and lower stresses. It is found that if the results are plotted with maximum stress as ordinates and the logarithm of the number of cycles to failure as abscissas, there result characteristic curves called S-N curves (Fig. 14). In steels, these curves are found to be approximately straight up to about 10,000,000 cycles and at about this point are found to level off so that below this stress no fatigue failure can be produced even with an indefinitely large number of cycles. Hence in testing steels, it is only necessary to establish

centage of the gage length), which occurs up to the fracture point in the tensile test. For comparable results, the ultimate elongation must be measured in a definite gage length and on a definite size of specimen, although specimens of geometrically similar shape but of different sizes will give commercially comparable results. For specimens not geometrically similar, there is no satisfactory general rule by which their ductility can be compared and it is *necessary in all specifications that the shape and preferably the size of the specimen should be stated.*

In addition to the ultimate elongation, it is customary to measure the reduction of area of the cross section of the tensile specimen at the fracture. This is expressed in percent and is merely the loss of area expressed in terms of the original area. For round sections, the fracture is usually so nearly round as to be readily measured directly, but with specimens of other cross section the fracture is a distorted section which cannot be accurately measured, and in such cases reduction of area is ordinarily not reported.

Table 1. Strengths of Metals

Metal	Tensile strength, 1,000 lb per sq in.	Yield strength, 1,000 lb per sq in.	Ultimate elongation, percent	Reduction of area, percent	Brinell No.

Compressive strength of cast iron, 80,000 to 150,000 lb per sq in.

Compressive yield strength of all metals, except those cold worked, = tensile yield strength.

Gough, "Contact Corrosion under Pressure," *Nat. Phys. Lab. Rept., Dept. Ind. Sci. Research*, 1935, p. 150). Although any corroding agent is productive of severe corrosion fatigue, there is so much difference between the effects of "sea water" or of "tap water" from different localities that numerical values are not of much value.

In many structural elements, completely reversed stresses, as are used in determining the endurance limit, do not occur, and other limits of stress variation are encountered. Under such conditions, the **allowable range** may be determined approximately from the empirical graph shown in Fig. 15. Here the absolute values of the extreme stresses are plotted as ordinates and the average value of the two extremes as abscissas. The endurance limit is plotted above and below the origin, and the tensile strength is plotted as a single point whose ordinate and abscissa both equal the tensile strength. Straight lines are then drawn connecting the two endurance limit points with the tensile strength point, and any range between these two lines is allowable. Since the yield strength should not ordinarily be exceeded in design, the graph is usually cut off at this value. The compressive side of the graph is usually taken as being similar to the tensile side.

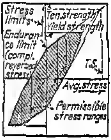

FIG. 15.—Permissible Stress Ranges in Fatigue.

Fatigue strength, as measured by the endurance limit in reversed bending, is not fundamentally related to any other property. However, for materials of a given type, there may be a relationship between the endurance limit and the tensile strength or between the endurance limit and hardness. For the plain carbon steels, annealed, the endurance limit ranges from 0.45 to 0.55 times the tensile strength and for some of the alloy steels and for the nonferrous materials, in general, the ratio is much lower. In direct tension-compression loading, as compared with the reversed bending tests described, the endurance limit is lower, ranging from 0.75 to 0.90 times the endurance limit in reversed bending. The endurance limit in reversed shear ranges from 0.50 to 0.60 times the endurance limit in reversed bending. For partly reversed stresses of any type, the construction shown in Fig. 15 may be used, taking the tensile strength as the upper point in the cases of bending and tension and ½ the tensile strength in the case of shear. The diagram for shear should be limited also by the value ½ times the yield strength.

Fatigue failure is particularly dangerous since the incipient cracks are often invisible, although they invariably originate at a surface, and the final failure may occur with disastrous suddenness in high-speed machinery or vehicles. However, the progress of the crack in its early stages is extremely slow (deForest, "The Rate of Growth of Fatigue Cracks," *Trans. A.S.M.E.*, 58, 1936, p. A23), and losses attendant on failure in service may be largely eliminated by periodic inspection by special means and rejection or repair of parts in which cracks have started. One of the best means for this inspection is the **Magnaflux method**, in which the part (necessarily ferromagnetic) is magnetized and covered with a fine magnetic powder. In the vicinity of a crack there is a disturbance of the magnetic flux and the magnetic powder gathers there, effectively marking the crack. With non-magnetic materials, other methods must be used, such as whitewashing the part and depending on the discoloration of oil seeping out of a crack to reveal such cracks, but none of these approaches the efficacy of the Magnaflux method on steel. Periodic inspection of all vital parts, primarily by the Magnaflux method, is rapidly

proportional elastic limit and the maximum torque in the torsion test. (For a method of obtaining stress-strain diagrams for shear, see Nadai, "Plasticity," McGraw-Hill, p. 126.) With most of the ordinary *ductile* steels, brasses, and aluminum alloys, the direct shear strength is in the vicinity of 0.6 to 0.7 of the tensile strength, and the apparent strength in torsion is 0.8 to 0.9 of the tensile strength.

Table 3. Mechanical Properties of Stone and Brick*

	Specific gravity	Compressive strength, lb per sq in.	Modulus of elasticity, lb per sq in.	Absorption of water, parts by weight	Coefficient of expansion per deg F	Modulus of rupture, per sq in.

Brick masonry						
In lime mortar...............		0.14 × compressive strength of brick				
In cement mortar.............		0.23 × compressive strength of brick				

* Other Strength Functions. Shearing strength of brick and stone is from 10 to 20 percent of the compressive strength; tensile strength is 4 percent of compressive strength; modulus of rupture is 15 percent of compressive strength. Poisson's ratio is 1/4.

Velocity of Testing. Within the usual speeds of commercial testing machines, the speed of testing does not cause any variation of the strengths of metals which is of commercial significance, except possibly in the yield point. Non-metallic materials, such as cloth, wood, rope, and plastics, are in general much more sensitive to testing speed, and attention must be paid to this factor and to the time of loading in service. With very slow loadings of metals, extending over a period of years, some slight reduction of strength may be expected, and under elevated temperatures or with certain metals *creep* (see p. 428) may occur. With extremely high loading speeds, obtained in machines specially constructed for the purpose or in shock and impact loadings of a structure, strengths may increase greatly over the usual values, and entirely new types of failure may occur (see p. 420).

Effect of Size. The strengths shown by large specimens are generally lower than those quoted for the usual 1/2 in. size as a result of the difficulties in heat-treatment and working of sections of large size, and for other, more obscure, reasons. Although no definite rules can be made, a reduction of 10 to 25 percent may be expected for the strength of a 3 in. piece as compared with a 1/2 in. piece. Very small sections, such as wires, often show much higher strengths than conventional sections, and in the case of glass fibers the strength of a 0.0001 in. diam filament has been found to be 20 times that of a 0.03 in. diam rod.

The character of the fracture under tension indicates the quality of the material, but is influenced by the speed and the method of producing fracture and by the shape of the test piece. A metal that is tough and fibrous may appear crystalline if broken quickly at a nicked section. Contraction is greatest in tough and ductile, and least in brittle, materials. The shape of fracture is usually a central flat surface of failure in tension, surrounded by a rim on which the metal shears. The extent of the rim is more pronounced when the ratio of shearing to tensile strength is less, is more developed in soft steels, becomes a complete cone in very soft materials, and vanishes in cast iron,

ferrous metals, are exceptions to the general rule in that they show low malleability and ductility and slightly higher strength through certain temperature ranges and, hence, should not be hot-worked at such temperatures (see p. 610). Tests by the Crane Co. on a wide range of metals and alloys, as reported by Bregowsky and Spring, in *The Valve World*, Jan., 1913, are given in Tables 6 and 7. See also Rudeloff, International Assoc. for Testing Materials, 1909, and "Symposium on Corrosion-resistant, Heat-resistant, and Electrical-resistance Alloys," *Proc. A.S.T.M.*, 24, Part II. For strengths at low temperatures, see p. 630.

Creep and Relaxation

Although the change in the static strengths of materials at elevated temperatures may occasionally be of design significance, there occurs at these temperatures, in most metals (and at room temperature for some metals,

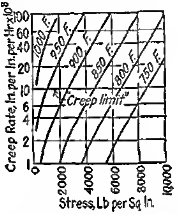

FIG. 16.—Creep Rates for 0.35 Carbon Steel.

such as lead), a slow deformation under stress, called **creep**, which may lead to excessive deformations or to fracture. Creep is generally assumed to proceed at a constant rate at any given temperature and stress; the total deformation at the end of any given time can then be calculated. The working stress should be so chosen that this total deformation during the desired life of the structure will not be excessive. A **creep limit**, which is defined as the stress which at a given temperature will result in 1 percent deformation in 10 years, or in 100,000 hr., has received a certain amount of recognition, but it is advisable to determine the proper stress for each individual case from diagrams of stress vs. creep rate, as shown in Fig. 16 (see Creep Data published by the A.S.T.M. and A.S.M.E., 1938).

Associated with creep, which deals with deformation under constant stress, is **relaxation**, which deals with the release of stress in structural elements that are deformed a predetermined amount and are expected to carry a load at this deformation, such as flange bolts in high-temperature steam service. Direct numerical correlation between relaxation and creep has not yet been generalized (Davenport, "Correlation of Creep and Relaxation Properties of Copper," *Trans. A.S.M.E.*, 40, 1938, p. A55), and relaxation design is not yet on a sound basis.

NOTES ON TABLE 7

[1] Bessemer steel, 0.093 percent carbon. [2] Cumberland cold-rolled shafting, 0.083 percent carbon. [3] Open-hearth steel, 0.084 percent carbon. [4] (Ni, 3.25; V, 0.45; C, 0.365), oil tempered. [5] 25 percent nickel. [6] 30 percent nickel; turned from 1 in. to 0.8 in. diam. [7] Turned to 0.75 in. diam from a 7/8 in. bar. [8] Cumberland shafting, 0.375 percent carbon. [9] Annealed (Cr, 0.49; V, 0.145; C, 0.722). [10] Rolled rod (Cu, 62.5; Zn, 35, Pb, 2.5). [11] Elephant (phosphor) bronze (Cu, 95.5; Sn, 4; P, 0.31).

this break in the curve in the vicinity of the 10,000,000 cycle point, and the corresponding stress is termed the **endurance limit**, or, less commonly, the **fatigue limit**. With the nonferrous metals, the curves exhibit no such definite break as in the case of the steels, and a true endurance limit should not be quoted. Values currently reported are usually obtained from tests running well over 10,000,000 cycles, and in careful practice as many as 500,000,000 cycles are used (see Templin, "Fatigue of Light Metal Alloys," *Metals Alloys*, 10, No. 8, p. 243).

Surface defects, such as roughness or scratches, and notches of shoulders, all reduce the fatigue strength of a part. With a notch of definite geometric form and known concentration factor, the reduction in strength is materially less than would be called for by the concentration factor itself, but the various metals differ widely in their susceptibility to the effect of roughness and concentrations, or **notch sensitivity**. Further, notch sensitivity seems to be higher, and ordinary fatigue strength lower, in large specimens, necessitating full-size tests in many instances (see Peterson, "Stress Concentration Phenomena in Fatigue of Metals," *Trans. A.S.M.E.*, 55, 1933, p. 157; and Buckwalter and Horger, "Investigation of Fatigue Strength of Axles, Press Fits, Surface Rolling and Effect of Size," *Trans. A.S.M.*, 25, Mar., 1937, p. 229). In addition to other factors, **corrosion** and **galling** (due to rubbing of mating surfaces) each cause great reduction of fatigue strengths, sometimes amounting to as much as 90 percent of the original endurance limit (see

Nitralloy	125	80	Magnesium alloys	20–45	7–17
Brasses, various	25–75	7–20			

Phosphor bronze. Rate 0.1, temp 400 (550) [700] {800}, stress 15 (6) [4] {1}; rate 0.01, temp 400 (550) [700], stress 8 (4) [2].

Nickel. Rate 0.1, temp 800 (1000), stress 20 (10).

70 *Cu*, 30 *Ni.* Rate 0.1, temp 600 (750), stress 28 (13–18); rate 0.01, temp 600 (750), stress 14 (8–9).

Aluminum alloy #17S (*Duralumin*). Rate 0.1, temp 300 (500) [600], stress 22 (5) [1.5].

Lead, pure (commercial) [0.03 percent Ca], at 110 F, for rate 0.1 percent the stress range, lb per sq in., is 150–180 (60–140) [200–220]; for rate of 0.01 percent, 50–90 (10–50) [110–150].

Hardness

Hardness has been variously defined as resistance to local penetration, to scratching, to machining, to wear or abrasion, and to yielding. The multiplicity of definitions, and corresponding multiplicity of hardness measuring instruments, together with the lack of a fundamental definition, indicates that hardness may not be a fundamental property of a material but rather a composite one including yield strength, work hardening, true tensile strength, modulus of elasticity, and others.

Scratch hardness is measured by Mohs scale of minerals (see p. 86) which is so arranged that each mineral will scratch the mineral of the next lower number. In recent mineralogical work and in certain microscopic metallurgical work, jeweled scratching points either with a set load or else loaded to give a set width of scratch have been used (see Talmadge, "Quantitative Standards for Hardness of the Ore Minerals," *Econ. Geol.*, **20**, 1925, p. 531; and Bierbaum, "The Microcharacter," *Trans. A.S.S.T.*, **18**, 1930, p. 1009). Hardness in its relation to machinability and to wear and abrasion is generally dealt with in direct machining or wear tests, and little attempt is made to separate hardness itself, as a numerically expressed quantity, from the results of such tests.

The resistance to localized penetration, or **indentation hardness**, is widely used industrially as a measure of hardness, and indirectly as an indicator of other desired properties in a manufactured product. The indentation tests described below are essentially non-destructive, and in most applications may be considered non-marring, so that they may be applied to each piece produced, and through the empirical relationships of hardness to such properties as tensile strength, fatigue strength, and impact strength, pieces likely to be deficient in these latter properties may be detected and rejected.

Brinell hardness is determined by forcing a hardened sphere under a known load into the surface of a material and measuring the diameter of the indentation left after the test. The **Brinell hardness number**, or simply the **Brinell number**, is obtained by dividing the load used, in kilograms, by the actual surface area of the indentation, in square millimeters. The result is a pressure, but the units are rarely stated.

$$B_r = P \Big/ \frac{\pi D}{2}(D - \sqrt{D^2 - d^2})$$

where B_r is the Brinell hardness number; P the imposed load, kg; D the diameter of the spherical indentor, mm; and d the diameter of the resulting impression, mm.

Hardened steel bearing balls may be used for hardness up to 500, but beyond this hardness especially treated steel balls or jewels should be used to

becoming standard practice in the transportation and high-speed machinery fields.

Surface fatigue occurs under highly concentrated compressive loading between two rolling members, such as in ball bearings, and results in a flaking off, or **spalling**, of the material of one or both surfaces. Aside from bearings, the only important case of surface fatigue occurs in gear teeth. Both these cases are covered by the specialized design rules of the respective industries (see Buckingham, "Dynamic Loads on Gear Teeth," publication of A.S.M.E.; Almen, "Lubricants and False Brinelling of Ball and Roller Bearings," *Mech. Eng.*, June, 1937; Stribeck, "Kugellager für beliebige Belastung," translated by Hess, *Trans. A.S.M.E.*, **29**, 1907, p. 367).

Strengths at Elevated Temperatures

In general, the strengths, such as elastic limit, yield point or yield strength, and tensile strength, of metals decrease with increasing temperature, whereas the ductility and malleability increase. In steel, the modulus of elasticity E decreases with increasing temperature. In most structural design, these strengths are of little significance since creep is likely to occur below the elastic limit, but where the loads are of short duration only they may be used in the ordinary manner. A few steels, and a number of non-

impression is measured by means of a medium-power compound microscope.

$$V = P/0.5393d^2$$

where V is the Vickers hardness number; P the imposed load, kg; and d the diagonal of indentation, mm. The Vickers method is more flexible and is considered to be more accurate than either the Brinell or the Rockwell, but the equipment is more expensive than either of the others (approx $1,500 against $400) and the Rockwell is somewhat faster in production work.

Among the other hardness methods may be mentioned the **Scleroscope**, in which a diamond-tipped "hammer" is dropped on the surface and the rebound taken as an index of hardness. This type of apparatus is seriously affected by the resilience as well as the hardness of the material and has largely been superseded by other methods. In the **Monotron** method, a penetrator is forced into the material to a predetermined depth and the load required is taken as the indirect measure of the hardness. This is the reverse of the Rockwell method in principle, but the loads and indentations are smaller than those of the latter. In the **Herbert pendulum**, a 1 mm steel or jewel ball resting on the surface to be tested acts as the fulcrum for a 4 kg compound pendulum of 10 sec period. The swinging of the pendulum causes a rolling indentation in the material, and from the behavior of the pendulum several factors in hardness, such as **work hardenability**, may be determined which are not revealed by other methods. Although the Herbert results are of considerable significance, the instrument is suitable for laboratory use only (see Herbert, "The Pendulum Hardness Tester," and "Some Recent Developments in Hardness Testing," *Engineer*, 135, 1923, pp. 390 and 686). In the **Herbert cloudburst** test, a shower of steel balls, dropped from a predetermined height, dulls the surface of a hardened part in proportion to its softness and thus reveals defective areas. A variety of **mutual indentation methods** (Cowdrey, "Hardness by Mutual Indentation," *Proc. A.S.T.M.*, 30, II, 1930, p. 559) in which crossed cylinders or prisms of the material to be tested are forced together, give results comparable with the Brinell test. These are particularly useful on wires and on materials at high temperatures.

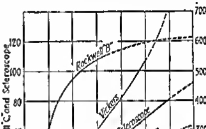

FIG. 17.—Hardness Scales.

The relation among the scales of the various hardness methods is not exact, since no two measure exactly the same sort of hardness and a relationship determined on steels of different hardnesses will be found only approximately true with other materials. The **Vickers-Brinell relation** is nearly linear up to at least 400, with the Vickers approximately 5 percent higher than the Brinell (actual values run from +2 to +11 percent) and nearly independent of the material. Beyond 500, the values become more widely divergent owing to the flattening of the Brinell ball. The **Brinell-Rockwell relation** is fairly satisfactory and is shown in Fig. 17. Approximate relations for the Shore Scleroscope are also given on the same plot.

The **hardness of wood** is defined by the A.S.T.M. as the load in pounds required to force a ball 0.444 in. diam into the wood to a depth of 0.222 in., the speed of penetration being ¼ in. per min. For a summary of the work in hardness to 1929, see Hankins, "Synopsis of Knowledge of Hardness Testing," *Proc. Inst. M.E.*, 1929, Part I, p. 317.

Testing of Materials

Testing Machines. Machines for the mechanical testing of materials usually contain elements (1) for gripping the specimen, (2) for deforming it, and (3) for measuring the load required in performing the deformation.

Table 7. Torsional Tests on Metals and Alloys Subjected to High Temperatures

(Torsional strength and elastic limit in in.-lb per sq in. Total twist in number of turns, with number of degrees excess. Test bars turned to 0.855 in. diam from 1¼ in. rods.)

Twist	180°	3 and 235°	4 and 300°	
Manganese Bronze:				
Torsional strength	61,630	37,630	8,980	
Elastic limit	22,040	13,060	3,260	
Twist	2 and 5°	3 and 110°	2 and 10°	

For notes see page 428.

Serrated grips may be used to hold ductile materials or the shanks of other holders in tension; a taper of 1 in 6 on the wedge faces gives a self-tightening action without excessive jamming. Ropes are ordinarily held by wet eye splices, but braided ropes or small cords may be given several turns over a fixed pin and then clamped. Wire ropes should be zincked into forged sockets (solder and lead have insufficient strength).

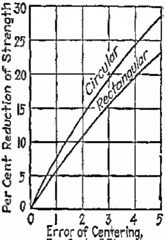

FIG. 18.—Effect of Centering Errors on Brittle Test Specimens.

Accuracy and Calibration. The A.S.T.M. (specification E4-36) requires that commercial machines shall have errors of less than 1 percent within the "loading range" when checked against acceptable standards of comparison at at least five suitably spaced loads. The "loading range" may be any range through which the preceding requirements for accuracy are satisfied, except that it shall not extend below 100 times the least load to which the machine will respond or which can be read on the indicator. Brinell-hardness machines are permitted errors up to 3 percent. The use of calibration plots or tables to correct the results of an otherwise inaccurate machine is not permitted under any circumstances. Machines with errors less than 0.1 percent have recently become commercially available (Tate-Emery, and others), and somewhat greater accuracy is possible in the most refined research apparatus.

Dead loads may be used to check machines of low capacity; accurately calibrated proving levers may be used to extend the range of available weights. Various elastic devices (such as the Morehouse proving ring) made of specially treated steel, with sensitive distortion measuring devices, and calibrated by dead weights at the Bureau of Standards, are made in capacities from 1,000 to 100,000 lb and are the most satisfactory means of checking the higher loads. In an emergency, a number of specimens may be cut from a uniform bar and half the number tested in the machine in question while the remainder are tested in a machine of known accuracy.

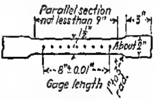

FIG. 19.—Tension Specimen for Plate Stock (A.S.T.M. E8-36).

In general, the **testing speed** should be such that the weighing mechanism will accurately follow the load on the specimen. Specified maximum testing speeds (A.S.T.M.) are: yield strength, ⅛ in. per min; tensile strength on ductile materials, 1½ in. per min; compression, 1 in. specimens, 0.05 in. per min; specimens 3 in. and over, 0.10 in. per min; cement-mortar briquettes, 575 lb per min min, 625 lb per min max; concrete and brick, 0.05 in. per min; wood beams 2 × 2 × 30, 0.10 in. per min; wood compression 2 × 2 × 8, 0.024 in. per min.

Standard **forms of test specimens** (A.S.T.M.) are shown in Figs. 19 to 25. In wrought materials, and particularly in those which have been cold-worked, different properties may be expected in different directions with respect to the direction of the applied work, and the test specimen should be cut from the

[a] Additional data. At creep rate **0.1** percent and 1000 (1600) F the stress is 18–25 (1); at creep rate 0.01 percent and 1500 F, the stress is 0.5.
[b] Additional data. At creep rate 0.1 percent and 1000 (1600) F the stress is 20–30 (1).
[c] Additional data. At creep rate 0.1 percent and 1600 F the stress is 3; at creep rate 0.01 and 1500 F, the stress is 2–3.

Additional temperatures (deg F) and stresses (in 1,000 lb per sq in.) for stated creep rates (percent per 1,000 hr) for wrought non-ferrous metals are as follows:

60–40 *brass*. Rate 0.1, temp. 350 (400), stress 8 (2); rate 0.01 temp 300 (350) [400], stress 10 (3) [1].

with a simple lever, as in the **Berry strain gage** (F. F. Metzger & Son, Philadelphia), the dial gage reads reliably to 0.0001 in. over gage lengths of 2 to 20 in. The **Huggenberger Tensometer** (Baldwin-Southwark Corp.) is a very light instrument employing a compound lever system magnifying about 1,000 times and giving readings to 0.00001 in. or better over gage lengths of 0.4 to 8 in. (see Vose, "Characteristics of the Huggenberger Tensometer," *Proc. A.S.T.M.*, 34, 1934, p. 862).

Optical gages have sometimes used microscopes, but their weight renders them extremely inconvenient, whereas the "optical lever" (light beam reflected from a tilting mirror) furnishes an extremely light and sensitive instrument. Tilting mirrors may be easily constructed for any use and can be arranged for any desired magnification, the most refined commercial type being the **Tuckerman gage** (American Instrument Co., Washington, D. C.). Interferometers are sensitive to one millionth inch, are self-calibrating, and can be arranged in numerous ways, but their reading is somewhat difficult (see Tuckerman, "Optical Strain Gages and Extensometers," *Proc. A.S.T.M.*, 23, 1923, p. 602; and Vose, "An Application of the Interferometer Strain Gage in Photoelasticity," *Trans. A.S.M.E.*, 57, 1935, p. A99). In the **deForest Scratch Gage** (Baldwin-Southwark Corp.), a sharp scriber is dragged over a polished target by the deformation, and the inscribed record is later observed under a microscope. Although the deformations recorded on the scratch gage cannot be read to much closer than 0.0001 in., it is the only mechanical device suitable for vibratory stresses and, in addition, is extremely light and cheap and furnishes a permanent record. Some of the more rugged tilting-mirror gages may be used for vibratory stresses at low frequencies.

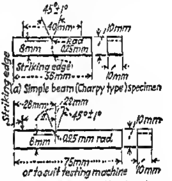

FIG. 25.—Impact Test Specimens (A.S.T.M. E23-34T).

The **electrical type of strain gage** is particularly adapted to vibratory stresses (see p. 525); some of the best types retain their calibration sufficiently well to be useful in measuring static stresses. Change in resistance is almost always employed, with a sensitive element similar to a carbon microphone in the older types (McCollum-Peters Telemeter, Baldwin-Southwark Corp.) and carbon or carbon-bearing strip (Ess Strip, Baldwin-Southwark) or special wire (Ruge-deForest, Baldwin-Southwark, and Davis-Carlson) in more recent types. The Ess Strip may be cemented directly to the surface to be investigated; the wire types may be made extremely sensitive, and it is claimed that as low as 3 lb per sq in. in steel may be detected with them. Changes in magnetic reluctance and in electrical-condenser capacity have also been used in strain gages, but their most satisfactory function seems to be as a null indicator rather than as a measuring device.

For a general indication of strain distribution, a "brittle varnish" ("Stresscoat," Magnaflux Corp., Chicago) may be spread into otherwise inaccessible places and used to indicate tensile stresses and their directions through the cracks that appear when the base material is deformed.

avoid flattening the indentor. The standard size ball is 10 mm and the standard loads 3,000 kg for steels and 500 kg for the softer non-ferrous metals, with 100 kg occasionally being used for very soft materials. If for special reasons any other size of ball is used, the load should be adjusted approximately as follows: for iron and steel, $P = 30D^2$; for brass, bronze, and other soft metals, $P = 5D^2$; for extremely soft metals, $P = D^2$ (see "Methods of Brinell Hardness Testing," A.S.T.M. Specification E10-27). Readings obtained with other than the standard ball and loadings should have the load and ball size appended, as such readings are only approximately equal to those obtained under standard conditions.

The size of the specimen should be sufficient to ensure that no part of the plastic flow around the impression reaches a free surface, and in no case should the thickness be less than 10 times the depth of the impression or the width less than 3 times the diameter of the impression. The load should be applied steadily and should remain on for at least 10 sec in the case of ferrous materials and 30 sec in the case of most non-ferrous materials. Longer periods may be necessary on certain soft materials that exhibit creep at room temperature. In testing thin materials, it is not permissible to pile up several thicknesses of material under the indentor, as the readings so obtained will invariably be lower than the true readings. With such materials, smaller indentors and loads, or different methods of hardness testing, are necessary.

In the standard Brinell test, the diameter of the impression is measured with a low-power hand microscope, but for production work there are available several testing machines which automatically measure the depth of the impression and from this give readings of hardness. Such machines should be frequently calibrated on test blocks of known hardness.

In the **Rockwell method** of hardness testing, the depth of penetration of an indentor under certain arbitrary conditions of test is determined. The indentor may be either a steel ball of some specified diameter, or a spherical-tipped conical diamond of 120 deg angle and 0.2 mm tip radius, called a "Brale." A *minor load* of 10 kg is first applied which causes an initial penetration and holds the indentor in place. Under this condition, the depth-measuring scale is set to its arbitrary maximum value of 130 if any of the balls are used, or to 100 if the Brale is used. A *major load* of 60, 100, or 150 kg is then applied under dashpot control and then removed, returning to the minor load of 10 kg. The hardness number may then be read directly from the scale which measures penetration, and this scale is so arranged that soft materials with deep penetrations give low hardness numbers.

A variety of combinations of indentor and major load are possible; the most commonly used are R_B using as indentor a $\frac{1}{16}$ in. ball and a major load of 100 kg and R_C using a Brale as indentor and a major load of 150 kg (see "Rockwell Hardness Testing of Metallic Materials," A.S.T.M. Specification E18-36).

As compared with the Brinell test, the Rockwell method makes a smaller indentation, may be used on thinner material, and is much more rapid since hardness numbers are read directly and need not be calculated. However, the Brinell test may be made without special apparatus and is somewhat more widely recognized for laboratory use. There is also a **Rockwell superficial hardness** test similar to the regular Rockwell, except that the indentation is much shallower.

The **Vickers** method of hardness testing is similar in principle to the Brinell in that it expresses the result in terms of the pressure under the indentor and uses the same units, kilograms per square millimeter. The indentor is a diamond in the form of a square pyramid with an apical angle of 136 deg, the loads are much lighter, varying between 2 and 120 kg, and the

Stress is an internal distributed force; it is the internal mechanical reaction of the material accompanying deformation. Stresses always occur in pairs. Stresses are **normal** [tensile stress (+) and compressive stress (−)]; and **tangential, or shearing.**

Intensity of stress, or unit stress, S (lb per sq in.) is the amount of force per unit of area of surface (Fig. 3). P is the load acting through the center of gravity of the area. The uniformly distributed normal stress is

$$S = P/A$$

When the stress is not uniformly distributed, $S = dP/dA$.

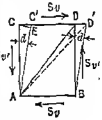

FIG. 2.

A long rod will stretch under its own weight G and a terminal load P (see Fig. 4). The total elongation e is that due to terminal load plus that due to one-half the weight of the rod considered as acting at the end.

$$e = [Pl + (Gl/2)]/AE$$

The maximum stress is at the upper end.

When a load is carried by several paths to a support, the different paths take portions of the load in proportion to their stiffness, which is controlled by material (E) and by design.

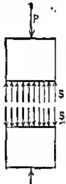

FIG. 3.

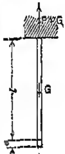

FIG. 4.

Example. Two pairs of bars rigidly connected (with the same elongation) carry a load P_0 (Fig. 5). A_1, A_2 and E_1, E_2 and P_1, P_2 and S_1, S_2 are cross sections, moduli of elasticity, loads and stresses of the bars, respectively; e = elongation.

$e = P_1l/(E_1A_1) = P_2l/(E_2A_2)$; $P_0 = 2P_1 + 2P_2$;
$S_2 = P_2/A_2 = \frac{1}{2}[P_0E_2/(E_1A_1 + E_2A_2)]$ and $S_1 = \frac{1}{2}[P_0E_1/(E_1A_1 + E_2A_2)]$.

Temperature Stresses. When the deformation arising from change of temperature is prevented, temperature stresses arise that are proportional to the amount of deformation that is prevented. Let a = coefficient of expansion per degree of temperature, l_1 = length of bar at temperature t_1, and l_2 = length at temperature t_2. Then

$$l_2 = l_1[1 + a(t_2 - t_1)]$$

If, subsequently, the bar is cooled to a temperature t_1, the proportionate deformation is $s = a(t_2 - t_1)$ and the corresponding unit stress $S = Ea \times (t_2 - t_1)$. For **coefficients of expansion**, see p. 298. In the case of steel, a change of temperature of 12 F will cause a unit stress of 2,340 lb per sq in.

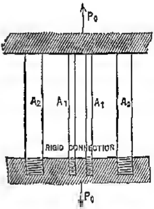

FIG. 5.

Shearing stresses (Fig. 2) act tangentially to the surface of contact and do not change length of sides of elementary volume; they **change the angle between faces** and the **length of diagonal.** Two pairs of shearing stresses must act together. **Shearing stress intensities are of equal magnitude on all four faces of an element.** $S_v = S_v'$ (Fig. 6).

Some machines (ductility testers) omit the measurement of load and substitute a measurement of deformation, whereas other machines include the measurement of both load and deformation through apparatus either integral with the testing machine (stress-strain recorders) or auxiliary to it (strain gages). In most general-purpose testing machines, the deformation is controlled as the independent variable and the resulting load measured, and in many special-purpose machines, particularly those for light loads, the load is controlled and the resulting deformation is measured. Special features may include those for constant rate of loading (pacing disks), for constant rate of straining, for constant load maintenance, and for cyclical load variation (fatigue).

A nut and screw combination, driven through clutches and change gears, was formerly common for **producing deformation**, but this arrangement has been largely superseded by a pump and hydraulic cylinder. The hydraulic arrangement is quieter, more flexible in control, and more durable, but cannot maintain constant deformation for any length of time on account of leakage. In **weighing light loads**, direct weights are accurate, but unless lead shot or water is used small variations in load are inconvenient. Ordinary springs used for this purpose are not sufficiently accurate, but the recently developed "Iso-Elastic" spring (John Chatillon & Sons, New York) has negligible errors. For larger loads, a reducing device with a **hydraulic weighing system** has largely displaced the lever system. Accurately lapped pistons may be made nearly frictionless; in some systems, an oscillatory rotation imposed on either the piston or the cylinder is used to remove any remaining friction. In the Emery hydraulic support, the load is taken by liquid pressure and is applied through a piston of considerable clearance sealed to the cylinder wall by a flexible flat metal diaphragm; although only minute displacement is possible, this system possesses great accuracy and sensitivity. For weighing the reduced load of a lever system, there may be used dead weights (lead shot), gravity pendulums, scale-and-rider combinations, or Iso-Elastic springs. In hydraulic systems, the liquid pressure is occasionally balanced by hydrostatic head, but may be transferred to a mechanical force through small pistons or Emery supports and balanced as for lever systems. Specially accurate pressure gages may be used (Emery-Tatnall system, Baldwin-Southwark Corp., Philadelphia); in the Tate-Emery system (Baldwin-Southwark), the pressure gage element is used as a null indicator, being balanced by Iso-Elastic springs, and gives particularly accurate and sensitive readings. Many systems have included means of **recording automatically** the load and deformation of the test piece, but few have been satisfactory until recent years (Emery-Tatnall and Tate-Emery). (For further information, see Gibbons, "Materials Testing Machines," Instruments Publishing Co., also in *Instruments*, 7, 8, 1934–1935, and *Bull. A.S.T.M.*, Oct., 1939.)

Grips should not only hold the test specimen against slippage but should also apply the load in the desired manner. Centering of the load is of great importance in compression testing, and should not be neglected in tension testing if the material is brittle. Figure 18 shows the theoretical errors due to off-center loading; the results are directly applicable to compression tests using swivel loading blocks. Swivel (ball-and-socket) holders or compression blocks should be used with all except the most ductile materials, and, in compression testing of brittle materials (concrete, stone, brick), any rough faces should be smoothly capped with plaster of Paris or, for greater strength, a mixture of two-thirds plaster of Paris and one-third Portland cement.

For an I-shaped cross section (Fig. 10*d*),

$$S_s \text{ (max)} = \frac{3}{4}\frac{Q}{a}\frac{bc^2 - (b-a)f^2}{bc^3 - (b-a)f^3} \text{ for } y = 0.$$

ELASTICITY

Elasticity is the ability of a material to return to its original dimensions after the removal of stresses. The **elastic limit** S_p is the limit of stress within which the deformation completely disappears after the removal of stress; *i.e.*, no set remains (see p. 414).

Hooke's law states that, within the elastic limit, deformation produced is proportional to the stress. Unless modified, the deduced formulas of mechanics apply only within the elastic limit. Beyond this, they are modified by experimental coefficients, as, for instance, the modulus of rupture.

The modulus of elasticity (pounds per square inch) is the ratio of the increment of unit stress to increment of unit deformation within the elastic limit.

The modulus of elasticity in tension, or Young's modulus,

$$E = \text{unit stress/unit deformation} = Pl/Ae.$$

The modulus of elasticity in compression is similarly measured.

The modulus of elasticity in shear or coefficient of rigidity, $G = S_s/d$ where d is expressed in radians (see Fig. 2).

The bulk modulus of elasticity K is the ratio of normal stress, applied to all six faces of a cube, to the change of volume.

Change of volume under normal stress. Let l, d, and b represent length, width, and thickness; μ = Poisson's ratio; s = unit deformation. Then deformed volume $= (1 + s)l(1 - \mu s)b(1 - \mu s)d \approx (1 + s - 2\mu s)lbd$. Fractional change of volume $\approx (1 - 2\mu)s$. When μ is less than $\frac{1}{2}$, the volume is increased in tension and decreased in compression. For steel ($\mu = \frac{1}{3}$), change of volume is about 1/3,000 part at the elastic limit.

The following relationships exist between the modulus of elasticity in tension or compression E, modulus of elasticity in shear G, bulk modulus of elasticity, K, and Poisson's ratio μ:

$$E = 2G(1 + \mu)$$
$$G = E/2(1 + \mu)$$
$$\mu = (E - 2G)/2G$$
$$K = E/3(1 - 2\mu)$$
$$\mu = (3K - E)/6K$$

Resilience U (in.-lb) is the potential energy stored up in a deformed body. The amount of resilience is equal to the work required to deform the body from zero stress to stress S, when S does not exceed the elastic limit. For normal stress, resilience = work of deformation = average force times deformation $= \frac{1}{2}Pe = \frac{1}{2}AS \times Sl/E = \frac{1}{2}S^2V/E$.

Modulus of resilience U_p (in.-lb per cu in.), or **unit resilience,** is the elastic energy stored up in a cubic inch of material at the elastic limit. For normal stress,

$$U_p = \tfrac{1}{2}S_p^2/E$$

The unit resilience for any other kind of stress, as shearing, bending, torsion, is a constant times one-half the square of the stress divided by the appropriate modulus of elasticity. For values, see Table 1.

parent material in such a way as to give the strength in the desired direction. With the exception of fatigue specimens and specimens of extremely brittle materials, surface finish is of little practical importance, although extreme roughness tends to decrease the ultimate elongation.

Strain Gages

For the measurement of deformations of less than 0.01 in., special strain gages should be attached to gage points, on the surface of the specimen, remote from the grips. These gages magnify the deformations by mechanical, optical, or electrical means and indicate visually or on a recording drum or oscillograph.

Mechanical gages include the micrometer screw and, more recently, the dial gage which can be obtained accurate to 0.0001 in. (Ames). Combined

structures; the Forest Products Laboratory of the U. S. Department of Agriculture has issued data for the design of timber structures. Manufacturers and engineers have also formulated allowable unit stresses for the guidance of designers. These specifications are undergoing constant revision with the gain of more accurate knowledge of the factors on which the factor of safety is based.

Consideration having been given to the several factors mentioned above, the designer may be guided by the following procedures for determining allowable unit stresses at normal temperature.

Static Loading. For ductile materials, an allowable unit stress equal to one-third to two-thirds (commonly one-half) of the unit stress at the yield point, and, for brittle materials, an allowable unit stress equal to one-sixth the ultimate unit stress will ordinarily provide for conservative designs. Thus for medium carbon steel, the allowable unit stress would be $35{,}000/2 = 17{,}500$ lb per sq in. and for cast iron it would be $24{,}000/6 = 4{,}000$ lb per sq in.

Dynamic Loading. For cases where the stress varies from a positive maximum to a negative maximum of the same amount, the allowable unit stress of one-third of the endurance limit is recommended for ordinary engineering materials.

Where **static and variable stresses** are **superimposed**, Soderberg recommends that the factor of safety be found from $1/n = s_0/s_y + Ks_r/s_e$ where n = factor of safety, s_0 = static loading, allowable unit stress, s_y = stress at the yield point, K = a factor to allow for stress concentrations or the effect of discontinuities (see p. 421), s_r = allowable unit stress for dynamic loading, and s_e = endurance limit.

IMPACT ON BARS

A **static load** is one at rest. **Dynamic loads** arise from impact. A **suddenly applied load** arises when a load that is just touching a bar is suddenly released. The velocity of approach is zero, the load is constant throughout the entire deformation, and the internal force in the bar increases from zero to some value AS. The stresses and deformations are double those due to an equal static load. G = weight producing a suddenly applied load. e = maximum elongation. P = internal force accompanying e. Work of weight Ge equals internal resilience $\frac{1}{2}Pe$. Therefore, $P = 2G$. The bar springs back and oscillates.

An **impact loading** occurs when a moving weight strikes the end of a bar. The velocity of impact is v. If the elastic limit is not exceeded, the external work of the moving weight falling from height h equals Gh, and also equals the resilience developed. P, S, and e are, respectively, dynamic force, stress, and elongation in bar. $G(h + e) = \frac{1}{2}Pe$. Let e' and S' be the elongation and stress which would accompany G if it acted as a static load. $G/e' = P/e$. Then

$$S = S' + S'[1 + (2h/e')]^{\frac{1}{2}}$$
$$e = e' + e'[1 + (2h/e')]^{\frac{1}{2}}$$

The value of e' is small, and dynamic stresses and deformations are usually large and may exceed the elastic limit. It is here assumed that the entire energy of the weight produces elastic deformation in the bar only, *i.e.*, that the supports are rigid and there is no friction.

Materials show a higher elastic limit of deformation under impact than under static loads. E appears to be unchanged (*Proc. Roy. Soc.*, Feb., 1905).

Shearing	G		

DEFINITIONS AND SIMPLE STRESSES

Deformations are changes in form produced by external forces or loads that act on non-rigid bodies. Deformations are **longitudinal**, e, a lengthening (+) or shortening (−) of the body; and **angular**, d, a change of angle between the faces.

Unit deformation (dimensionless number) is the deformation in unit distance. Unit longitudinal deformation $s = e/l$ (Fig. 1). Unit angular deformation tan d equals d approx (Fig. 2).

Accompanying a longitudinal deformation e is a **lateral** deformation e' (Fig. 1). The ratio of s'/s is **Poisson's ratio** μ. Values of μ are: glass, 0.244; brass, 0.333; copper, 0.333; cast iron, 0.270; wrought iron, 0.278; steel, 0.303; lead, 0.430; concrete, 0.10 to 0.20 at working stresses and 0.25 at higher stresses.

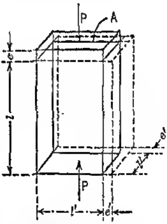

FIG. 1.

$$N = S\cos^2 a + S'\sin^2 a \quad (1)$$
$$T = (S - S')\sin a\cos a \quad (2)$$

$N_{max} = S$ or S' and $T_{max} = \frac{1}{2}(S - S')$ when $a = 45$ deg. If $a + a' = 90$ deg, $N + N' = S + S'$ and $T = T'$. The resultant stress R is the resultant of N and T. $R = \sqrt{N^2 + T^2}$. The direction angle of R is b, where $\sin b = \sin 2a\,(S - S')/2R$.

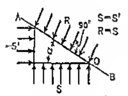

FIG. 13.

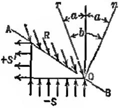

FIG. 14.

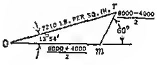

FIG. 15.

Special Cases under Case II. (a) If $+S = +S'$ (Fig. 13), $T = 0$, $R = S = S'$, and direction of R is normal. (b) If $+S = -S'$ (Fig. 14), $R = S = S'$, and *direction angle of $R = 2a$. S bisects the angle nOr.*

Example. The metal in a steam boiler is subjected to a unit stress of 8,000 lb per sq in. in a circumferential direction and 4,000 lb per sq in. in a longitudinal direction. Find the stresses on a plane the normal to which makes an angle of 30 deg with the direction of the 8,000 lb stress. From (1) and (2).

Normal stress $N = 8000\cos^2 30° + 4000\sin^2 30° = 7{,}000$ lb per sq in.
Tangential stress $T = (8000 - 4000)\sin 30°\cos 30° = 1{,}730$ lb per sq in.
Resultant stress $R = \sqrt{7000^2 + 1730^2} = 7{,}210$ lb per sq in.

$\sin b = \sin(2 \times 30°)(8000 - 4000)/(2 \times 7210) = 0.24023$, whence angle b, or the direction angle of R, is 13° 54'. For graphical solution, see Fig. 15.

A block (Fig. 16) is acted upon by three pairs of normal stresses S_x, S_y, and S_z. The deformation e_x along axis X is due to S_x modified by the lateral effects of S_y and S_z (see p. 437). When the stresses are all of the same sign, $e_x = (S_x/E) - [(S_y + S_z)/nE]$, where n = reciprocal of Poisson's ratio, whence

$$Ee_x = S_x - [(S_y + S_z)/n]$$
$$Ee_y = S_y - [(S_x + S_z)/n]$$
$$Ee_z = S_z - [(S_x + S_y)/n]$$

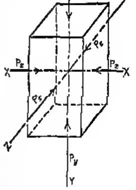

FIG. 16.

When the stresses are of different sign, corresponding changes occur in the formulas. The product Ee is regarded as a stress. The **apparent stress** is S, but the **true stress** $T = Ee$.

Elastic strength under compound stress is fixed, by three separate theories, as a certain value of either (1) the maximum principal apparent stress; (2) the true stress accompanying maximum principal deformation; or (3) the maximum shearing stress.

For example, metal in a boiler shell is under a hoop tension S_x and a longitudinal tension $S_y = \frac{1}{2}S_x$. According to (1), metal will begin to fail when S_x equals the elastic limit of the metal, regardless of the presence of S_y. According to (2), the necessary stress at failure is the true stress $T_x = Ee_x = S_x - S_y/n$. When $n = 3$, $T_x = \frac{5}{6}S_x$. That is, a hoop tension one-fifth greater than the elastic limit under simple stress, as

In the presence of **pure shear on external faces** (Fig. 6), the **resultant stress** S on one diagonal plane at **45 deg** is pure tension and on the other diagonal plane pure compression; $S = S_v = S'_v$. S on diagonal plane is called "diagonal tension" by writers on reinforced concrete. Failure under

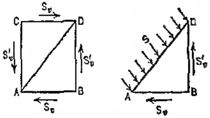

FIG. 6.

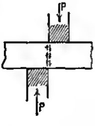

FIG. 7.

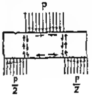

FIG. 8.

pure shear is difficult to produce experimentally, except under torsion and certain special cases. Figure 7 shows an ideal case and Fig. 8 a common form of test piece that introduces bending stresses.

Let Fig. 9 represent the section of area A on which a shearing force Q acts. Then, if pure shear should exist, $S_v = Q/A$. This would be uniformly distributed over the area A. When shear **is accompanied by bending (horizontal shear in beams)**, the unit shear S_v increases from the extreme fiber to the neutral axis OX. The unit shear parallel to axis OX at any point y distant from the neutral axis as at P (Fig. 9) is

$$S_v = \left(Q\int_y^e yz\,dy\right)/Iz$$

where I is the moment of inertia of the cross section about OX.

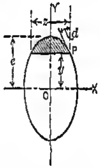

FIG. 9.

For a rectangular cross section (Fig. 10a),

$$S_v = \frac{3}{2}\frac{Q}{bh}\left[1 - \left(\frac{2y}{h}\right)^2\right]; \qquad S_v\ (\text{max}) = \frac{3}{2}\frac{Q}{bh} = \frac{3}{2}\frac{Q}{A},\ \text{for } y = 0.$$

For a circular cross section (Fig. 10b),

$$S_v = \frac{4}{3}\frac{Q}{\pi r^2}\left[1 - \left(\frac{y}{r}\right)^2\right]; \qquad S_v\ (\text{max}) = \frac{4}{3}\frac{Q}{\pi r^2} = \frac{4}{3}\frac{Q}{A},\ \text{for } y = 0.$$

For a circular ring (thickness small in comparison with the major diameter), $S_v\ (\text{max}) = 2Q/A$, for $y = 0$.

FIG. 10a.

FIG. 10b.

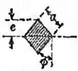

FIG. 10c.

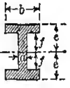

FIG. 10d.

For a square cross section (diagonal vertical, Fig. 10c),

$$S_v = \frac{Q\sqrt{2}}{a^2}\left[1 + \frac{y\sqrt{2}}{a} - 4\left(\frac{y}{a}\right)^2\right]. \qquad S_v\ (\text{max}) = 1.591\,\frac{Q}{A},\ \text{for } y = \frac{e}{4}.$$

obtainable thicknesses of wall. The apparent fiber stress under which the different tubes failed varied from about 7,000 lb per sq in. for the relatively thinnest to 35,000 lb per sq in. for the relatively thickest walls. Since the average yield point of the material was 37,000 and the tensile strength 58,000 lb per sq in., it would appear that the strength of a tube subjected to a collapsing fluid pressure is not dependent alone upon either the elastic limit or ultimate strength of the material constituting it. Prof. Stewart therefore suggests as a substitute for formula (a) the following:

$$P = 50{,}210{,}000(t/D)^3 \qquad (c)$$

The experiments by Stewart are considered to be the most reliable.

Carman (*Univ. Ill. Eng. Exp. Sta. Bull.* No. 5, June 1, 1906) states that the portion affected by collapse from hydraulic pressure is generally not greater in length than $12D$, that for greater lengths the collapsing pressure is independent of the length, and that the often-quoted law of Fairbairn type, in which the collapsing pressure varies inversely as the length, is only true for short tubes from $4D$ to $6D$ in length.

Carman's formulas are as follows:

For thin cold-drawn seamless steel tubes: $P = 50{,}200{,}000(t/D)^3$.

For thin brass tubes: $P = 25{,}150{,}000(t/D)^3$.

For thick cold-drawn seamless steel tubes: $P = 95{,}520(t/D) - 2090$.

For thick lap-welded steel tubes: $P = 83{,}270(t/D) - 1025$.

For thick brass tubes: $P = 93{,}365(t/D) - 2474$.

Limits of (t/D) are below 0.025 for thin tubes and above 0.03 for thick tubes.

When (t/D) is less than 0.06, **Carman's approximate formulas** are:

For cold-drawn seamless steel tubing, $P = 1{,}000{,}000(t/D)^2$.

For lap-welded steel, $P = 1{,}125{,}000(t/D)^2$.

These approximate formulas are stated to give satisfactory rough values for tubes of the most common commercial thicknesses.

A. E. H. Love gives the following **rational formulas**: $P = [2E/(1 - m^2)] \times (t/D)^3$ **for thin tubes** and $P = 2S_c[(t/D) - (t/D)^2]$ (special case of Lamé's general formula—see below) **for thick tubes**, where S_c is the ultimate compressive strength (yield point), lb per sq in. The average values of these constants for steel are: $E = 30{,}000{,}000$; $\mu = 0.295$; $S_c = 40{,}000$; and for brass: $E = 14{,}000{,}000$; $\mu = 0.357$; $S_c = 11{,}000$. Hence,

For thin steel tubes: $P = 65{,}720{,}000(t/D)^3$.

For thick steel tubes: $P = 80{,}000[(t/D) - (t/D)^2]$.

For thin brass tubes: $P = 32{,}090{,}000(t/D)^3$.

For thick brass tubes: $P = 22{,}000[(t/D) - (t/D)^2]$.

The **correction factor** for ellipticity and variation in thickness is $C = (D_{min}/D_{max})^3(t_{min}/t_{max})^3$. **Love's formula** becomes $P = [2CE/(1 - \mu^2)] (t/D)^3$ **for thin tubes**, in which $C = 0.69$ for Stewart's lap-welded steel flues, t = average thickness and D = maximum outside diameter, both in inches. **Lamé's formula** becomes $P = 2CS_c(t/D)[1 - C(t/D)^2]$ **for thick tubes**, in which $C = 0.8$.

Hollow sphere with normal pressure P. Pressure on meridian plane $= \pi r^2 P$. Tension or compression per lineal unit of shell $= \pi r^2 P/2\pi r = Pr/2$. Unit stress $S = Pr/2t$. The material carries an equal stress at right angles. True stress $T = S - (S/n) = Pr/3t$.

In thick cylinders (Fig. 18), **the stress is not uniformly distributed.** The hoop tension in the cylinder under internal pressure is greatest at the interior and diminishes toward the exterior. An interior hoop, from Fig. 18, is shown in Fig. 19. Cylinder unit pressure at bore $= p_1$. Radial internal

Unit rupture work U_R, sometimes called **ultimate resilience**, is measured by the area of the stress-deformation diagram to rupture.

$$U_R = \tfrac{1}{3}e_u(S_y + 2S_M), \text{ approx}$$

where e_u is the total deformation at rupture.

For structural steel, $U_R = \frac{1}{3} \times \frac{27}{100} \times [35{,}000 + (2 \times 60{,}000)] =$ 13,950 in.-lb per cu in.

Example 1. A load $P = 40{,}000$ lb compresses a wooden block of cross sectional area $A = 10$ sq in. and length = 10 in., an amount $e = \frac{4}{100}$ in. Stress $S = \frac{1}{10} \times 40{,}000 = 4{,}000$ lb per sq in. Unit elongation $s = \frac{4}{100} \div 10 = \frac{1}{250}$. Modulus of elasticity $E = 4{,}000 \div \frac{1}{250} = 1{,}000{,}000$ lb per sq in. Unit resilience $U_p = \frac{1}{2} \times 4{,}000 \times 4{,}000/1{,}000{,}000 = 8$ *in.-lb per cu in.*

Example 2. A weight $G = 5{,}000$ lb falls through a height $h = 2$ ft; V = number of cubic inches required to absorb the shock without exceeding a stress of 4,000 lb per sq in. Neglect compression of block. Work done by falling weight $= Gh = 5000 \times 2 \times 12$ in.-lb. Resilience of block $= V \times 8$ in.-lb $= 5000 \times 2 \times 12$. Therefore, $V = 15{,}000$ cu in.

ALLOWABLE UNIT STRESSES

The unit stresses used in the proportioning of machines and structures are called allowable unit stresses or **working stresses**. Unless the part is to be designed to fail under a single application of the load, the allowable stress is less than the ultimate stress. The ratio of the ultimate stress to the allowable stress is called the **factor of safety**. Since the stress at the yield point frequently limits the allowable unit stress, the factor of safety is sometimes defined as the ratio of the stress at the yield point to the allowable unit stress.

The magnitude of the **factor of safety** should be determined as a result of a consideration of the following factors: incorrect assumptions on which the computations are based; effects of temperature changes and initial stresses; possible increases of loads; effect of repetitions of stress (see p. 422); variations in the material and inaccuracies in workmanship; defects in the material; deterioration of the material; the effects of dynamic loads; effects of discontinuities due to notches, sharp fillets, and holes (see p. 421).

Numerous organizations have issued specifications which in their judgment provide for adequate designs. The A.S.M.E. has issued a code for the design of pressure vessels; the American Institute of Steel Construction specifications for steel buildings have been adopted in the building codes for many cities; the A.W.S. recommends allowable unit stresses to use in welded

Thick Cylinders with Shrinkage Rings. In these, it can be assumed that the stress under internal pressure is uniformly distributed over each ring, provided the ratio r/t is great.

Referring to Fig. 21, let t = sectional area (sq in.) of the cylinder for unit length in an axial direction; f = sectional area of the shrinkage rings per unit length of cylinder; S_1 = tensional hoop stress in hollow cylinder, lb per sq in.; S_2 = tensional hoop stress in shrinkage rings, lb per sq in.; p = interior pressure, lb per sq in.; and r = interior radius of cylinder, in. Then,

$$f = rp/[S_1(t/f) + S_2]$$

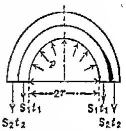

FIG. 21.

If the rings are shrunk on and R = outer radius of the inner cylinder; $R(1 - K)$ = inner radius of the rings before shrinking; $C_1 = 1/E_1$ for the inner cylinder; $C_2 = 1/E_2$ for the shrinkage rings; e_1 and e_2 = unit strains respectively in the inner cylinder and shrinkage rings when cold, then $K = e_1 + e_2 = C_2S_2 - C_1S_1$, and $e_1 = K/[1 + (C_2t/C_1f)]$.

The compressive stress in the cylinder before the pressure p is applied is $S' = e_1/C_1$; and the tensional stress in the shrinkage ring before the pressure p is applied is $S'' = e_2/C_2$. The pressure p causes a tensional stress of $S_1 + S'$ in the cylinder and of $S_2 - S''$ in the shrinkage rings.

The difference K found in this way is a minimum. This difference has to be increased, however, depending upon the condition of the surfaces of the cylinder and rings. If the rings are made of tough material, K may be increased considerably, as the effect is only to produce permanent expansion in the rings, while the inner cylinder will be compressed, thereby diminishing its working tensional stress.

The difference in temperature when the rings are forced on should be $d = K/c_w$, where c_w is the coefficient of expansion of the shrinkage ring.

Oval Hollow Cylinders. In Fig. 22, let a and b be the semiminor and semimajor axes. The bending moments at A and C will then be

$$M_0 = (pa^2/2) - (pI_x/2S) - (pI_y/2S)$$
$$M_1 = M_0 - p(a^2 - b^2)/2$$

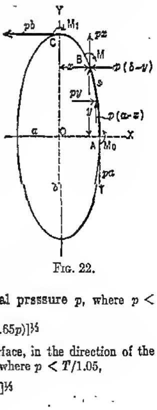

FIG. 22.

where I_x and I_y are the moments of inertia of the arc AC about the x and y axes, respectively. The bending moment at any point will be

$$M = M_0 - (pa^2/2) + (px^2/2) + (py^2/2).$$

Thick Hollow Spheres. With an internal prsssure p, where $p < T/0.65$,

$$r_2 = r_1[(T + 0.4p)/(T - 0.65p)]^{1/3}$$

The maximum tensile stress is on the inner surface, in the direction of the circumference. With an external pressure p, where $p < T/1.05$,

$$r_2 = r_1[T/(T - 1.05p)]^{1/3}$$

In both cases T is the true stress (see p. 444).

As on axial bars, **impact on beams** causes severe dynamic stresses. A weight W falling from height h on the center of a simple beam produces a maximum dynamic deflection f and a dynamic fiber stress S. Let f' and S' be the deflection and stress caused by W acting as a static load. By similar reasoning,

$$S = S' + S'[1 + (2h/f')]^{1/2} \tag{1}$$
$$f = f' + f'[1 + (2h/f')]^{1/2} \tag{2}$$

W must be large compared with the weight of the beam; otherwise, on account of the inertia of the beam, the energy will be used in local damage. Supports are rigid, and there is no friction.

The effect of inertia may be computed by the laws of collision of bodies. Assume impact **entirely inelastic.** nWh is the fractional part of the energy, producing elastic deformation in the beam or bar. W' = weight of beam or bar; W = weight of falling body; $m = W'/W$.

For longitudinal impact on a bar, $n = (1 + \frac{1}{3}m)/(1 + \frac{1}{2}m)^2$.

For center impact on a simple beam, $n = (1 + \frac{17}{35}m)/(1 + \frac{5}{8}m)^2$.

If the beam is fixed at the ends, use $\frac{13}{35}$ instead of $\frac{17}{35}$ and $\frac{1}{2}$ instead of $\frac{5}{8}$. For a cantilever struck at the end, use $\frac{33}{140}$ instead of $\frac{17}{35}$ and $\frac{3}{8}$ instead of $\frac{5}{8}$. **To compute stresses and deflections,** the value of h in (1) and (2) should be multiplied by n.

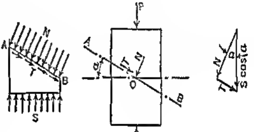

Fig. 11.

COMBINED STRESSES

The stresses treated here are *in one plane.* N is the unit normal stress, T the unit tangential stress on an internal inclined plane, S the unit stress on a plane normal to the geometric axis, P the external force, and R the resultant unit stress.

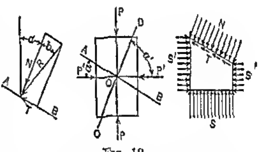

Fig. 12.

Stresses acting on different planes cannot be resolved or compounded like forces. The area upon which the stress acts must appear in the equation.

The resultant of several stresses acting together **on the same plane** is the geometric sum of their individual actions.

Case I. Force along One Axis (Fig. 11). The force P acts alone. The resultant stress on diagonal plane AB is resolved into a normal stress N and a tangential stress T.

$$N = S\cos^2 a \qquad T = S\sin a\cos a$$

The maximum value of T equals $\frac{1}{2}S$ when a equals 45 deg. The stresses on the diagonal plane CD (see Fig. 12) when $a + a' = \pi/2$, are $N' = S\sin^2 a$ and $T' = S\sin a\cos a$.

Case II. Forces along Two Right-angled Axes (Fig. 12). Here the forces P and P' act.

a distributed load may be replaced by its resultant acting at the center of gravity (cg) of the load area.

Simple Beams

The reactions at the support are computed. Thus, in Fig. 23, $\frac{1}{2}Wl = R_1l$, or $R_1 = \frac{1}{2}W$; $R_2 = \frac{1}{2}W$. In Fig. 24, $\frac{1}{3}Wl = R_1l$, or $R_1 = \frac{1}{3}W$; $R_2 = \frac{2}{3}W$. In general, the weight of the beam must be considered.

The **bending moment** (in ft-lb or in.-lb) at any section is the algebraic sum of the moments of the external forces on one side only of the section, or $M = \Sigma(Px)$. It is also equal to the moment of the internal forces or stresses at the section.

Examples: Uniform Load (Fig. 23). $M_A = \Sigma(Px)$ to left of point A at which moment is to be found. $M_A = \frac{1}{2}Wx - (wx \times \frac{1}{2}x)$. **Uniformly Varying Load** (Fig. 24). (Weight of beam neglected.) $M = \Sigma(Px) = \frac{1}{3}Wx - \frac{1}{2}kwx^2\frac{1}{3}x$, where k is a constant ($= h/l$) and w is the weight of the loading per unit of volume.

A **bending moment** that bends a beam convex downward is **positive** (+), and convex upward is **negative** (−).

The **shear** V (lb) is the algebraic sum of the external forces on one side only of the section and parallel to the section or $V = \Sigma P$. In Fig. 23, $V = \frac{1}{2}W - wx$. In Fig. 24, $V = \frac{1}{3}W - \frac{1}{2}kwx^2$

The moment and shear may be expressed by an ordinate drawn to scale at the section of the beam under consideration. A **bending moment diagram** is a series of such ordinates throughout the beam showing the variation of bending moment. A **shear diagram** is similarly constructed. Table 2 shows bending moment and shear diagrams for common cases of flexure, and gives values of reactions (R), moments (M), shears (Q), and deflections (f).

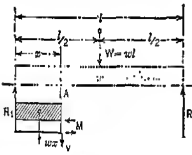

Fig. 23.

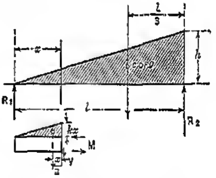

Fig. 24.

Maximum Safe Load on Steel Beams. To obtain maximum safe load (or maximum deflection under maximum safe load) for any of the conditions of loading given in Table 5, multiply the corresponding coefficient in that table by the greatest safe load (or deflection) for distributed load for the particular section under consideration as given in Table 4.

The following factors for reducing the load should be used when beams are long in comparison with their breadth:

Ratio of unsupported (lateral) length to flange width or breadth	20	30	40	50	60	70
Ratio of greatest safe load to calculated load	1	.9	.8	.7	.6	.5

shown in a testing machine, is required to cause failure. This method (2) is commonly used. According to (3), failure will begin when shearing stress $= \frac{1}{2}(S_x - S_y)$ is reached. Researches (1904–1908) by Hancock, Guest, and Coker point to truth of theory (3). This discussion is for elastic stresses and must not be extended to ultimate strength.

CYLINDERS AND SPHERES; TUBES

Thin Cylinders. In a thin envelope or ring (Fig. 17) subjected to an internal unit pressure p, the force of tension in ring P (hoop tension) in a unit length is constant and equal to pr. The uniform tensile stress S in the ring equals pr/t, or $t = pr/S$. An increase in t must be made to compensate for rivet holes in joints.

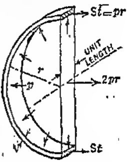

FIG. 17.

A portion of any circular curved ring under normal pressure carries a force $P = pr$. Internal pressure yields tension; external pressure yields compression.

If the **cylinder is closed at its ends,** a longitudinal stress S' acts. $S' = \frac{1}{2}rp/t = \frac{1}{2}S$. When $n = 3$ (see Poisson's ratio) the true stress $T = S - \frac{1}{3}S' = \frac{5}{6}S$.

Collapsing Pressure of Tubes. Tubes under external load may collapse. The following notation is used in the various formulas given for collapsing pressure:

P = collapsing pressure, lb per sq in. D = outside diam of tube, in.
E = modulus of elasticity. d = inside diam of tube, in.
μ = Poisson's ratio. l = length of tube, in.
t = thickness of tube, in.

For collapsing pressure, where l is not greater than $6D$, **Fairbairn's empirical formula** (1858) is: $P = 9{,}672{,}000(t^{2.19}/lD)$, or, more simply, $P = 9{,}675{,}600(t^2/lD)$.

For **large iron pipe flues,** diameters 30 to 50 in., **D. K. Clark's formula** is: $P = 200{,}000\ t^2/D^{1.75}$.

In 1906, two series of experiments were made by Prof. Reid T. Stewart on Bessemer steel lap-welded tubes (see *Trans. A.S.M.E.*, 28, p. 730). In one series, the tubes tested were $8\frac{5}{8}$ in. o. d. and of varying thickness and length, while in the other series they were 20 ft long and of varying thickness and diameter. The tests showed that all the old formulas were inapplicable to the wide range of conditions found in modern practice. Prof. Stewart found that the length of tube between transverse joints tending to hold it to a circular form has no practical influence upon the collapsing pressure of a commercial lap-welded steel tube, so long as this length is not less than about six diameters of tube.

As based upon his researches, **Stewart's formulas for the collapsing pressure of modern lap-welded Bessemer steel tubes** are as follows:

$$P = 1000[1 - \sqrt{1 - 1600(t^2/D^2)}] \qquad (a)$$
$$P = 86{,}670(t/D) - 1386 \qquad (b)$$

Formula (a) is for values of P less than 581 lb per sq in., or for values of (t/D) less than 0.023, while formula (b) is for values greater than these.

These formulas are correct for tubes that are 20 ft in length between transverse joints tending to hold them to a circular form, and at the same time are substantially correct for all lengths greater than about six diameters. They have been tested for seven diameters, ranging from 3 to 10 in., in all

$f = 0.01304\frac{Wl^3}{EI}$ (max)

compressive unit stress $= p$. External unit pressure $= p_2$. Hoop unit tension $= S$. Longitudinal unit stress $= S_L$.

In **Barlow's formula**, it is assumed that the volume of the metal does not change during expansion of the cylinder. Therefore S varies inversely as the radius squared. $Sr^2 = S_1r_1^2$.

The total internal pressure $2r_1p_1 = 2\int Sdr$, or $p_1 = S_1t/(r_1 + t)$.

In **Lamé's formula**, the cylinder is assumed to stretch longitudinally so that cross sections remain plane surfaces; the longitudinal deformation e_L is therefore constant. e_L is so connected with S and p that $Ee_L = S_L - [(S - p)/n]$. Therefore

$$S - p = \text{constant} = K \qquad (a)$$

Considering equilibrium of the internal hoop (*Fig. 19*),

$$2rp - [(r + dr)2(p \pm dp)] = 2Sdr, \text{ or}$$
$$d(pr)/dr = S \qquad (b)$$

Algebraic development of (a) and (b) leads to Lamé's formula

$$S = [r_1^2p_1 - r_2^2p_2 + (p_1 - p_2)r_1^2r_2^2/r^2]/(r_2^2 - r_1^2)$$

When $r = r_1$ and $p_2 = 0$, $S = S_1$ the hoop tension at the bore, or

$$S_1 = p_1(r_2^2 + r_1^2)/(r_2^2 - r_1^2) \qquad (1)$$

or $$r_2 = r_1[(S_1 + p_1)/(S_1 - p_1)]^{1/2}$$

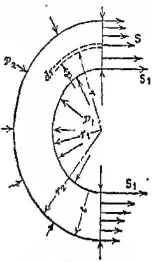

Fig. 18.

When $r = r_2$ and $p_2 = 0$, $S = S_2$ the hoop tension at exterior, or $S_2 = 2p_1r_1^2/(r_2^2 - r_1^2)$. If $r_2 = 2r_1$, $S_1 = 5p_1/3$ and $S_2 = \frac{2}{3}p_1$.

These stresses are apparent stresses. The true unit hoop stresses T are found by methods of p. 445.

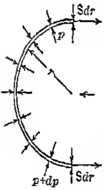

Fig. 19.

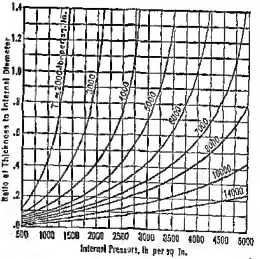

Fig. 20.

For **true stresses**, Hütte states that $r_2 = r_1[(T + 0.4p)/(T - 1.3p)]^{1/2}$ where T is the working tensile strength. Values of T from this equation are given in Fig. 20. When p is external this becomes $r_2 = r_1[T/(T - 1.7p)]^{1/2}$ when $p < T/1.7$ only.

* This table is convenient for wooden beams. For any other fiber stress S', multiply the values in table by $S'/1000$.

PRESSURE BETWEEN BODIES WITH CURVED SURFACES

Two Spheres. The radius A of the compressed area is obtained from the formula $A^3 = 0.68P(c_1 + c_2)/[(1/r_1) + (1/r_2)]$, in which P is the compressing force, c_1 and c_2 ($= 1/E_1$ and $1/E_2$) are reciprocals of the respective moduli of elasticity, and r_1 and r_2 are the radii. (Reciprocal of Poisson's ratio assumed to be $n = 10/3$.) The greatest compressive stress (in.-lb units) in the middle of the compressed surface will be $S_{max} = 1.5(P/\pi A^2)$, and

$$S^3_{max} = 0.235P[(1/r_1) + (1/r_2)]^2/(c_1 + c_2)^2$$

The total deformation of the two spheres will be Y, which is obtained from

$$Y^3 = 0.46P^2(c_1 + c_2)^2[(1/r_1) + (1/r_2)]$$

For $c_1 = c_2 = 1/E$, *i.e.*, two spheres with the same modulus of elasticity, it follows that $A^3 = 1.36\ P/E[(1/r_1) + (1/r_2)]$, $S^3_{max} = 0.059PE^2[(1/r_1) + (1/r_2)]^2$, and $Y^3 = 1.84P^2[(1/r_1) + (1/r_2)]/E^2$. If the radii of these spheres are also equal, $A^3 = 0.68Pr/E = 0.34Pd/E$; $S^3_{max} = 0.235PE^2/r^2 = 0.94PE^2/d^2$; and $Y^3 = 3.68P^2/E^2r = 7.36P^2/E^2/d$.

Sphere and Flat Plate. In this case, $r_1 = r$ and $r_2 = \infty$, and the above formulas become $A^3 = 0.68Pr(c_1 + c_2) = 1.36Pr/E$, and

$$S^3_{max} = 0.235P/r^2(c_1 + c_2)^2 = 0.059PE^2/r^2$$

Also $$Y^3 = 0.46P^2(c_1 + c_2)^2/r = 1.84P^2/E^2r.$$

Two Cylinders. The width b of the rectangular pressure surface is obtained from $(b/4)^2 = 0.29P(c_1 + c_2)/l[(1/r_1) + (1/r_2)]$, where r_1 and r_2 are the radii, and l the length.

$$S^2_{max} = (4P/\pi bl)^2 = 0.35P[(1/r_1) + (1/r_2)]/l(c_1 + c_2)$$

For cylinders with the same moduli of elasticity, $c_1 = c_2 = 1/E$, and $(b/4)^2 = 0.58P/El[(1/r_1) + (1/r_2)]$; and $S^2_{max} = 0.175PE[(1/r_1) + (1/r_2)]/l$. When $r_1 = r_2 = r$, $(b/4)^2 = 0.29Pr/El$, and $S^2_{max} = 0.35PE/lr$.

Cylinder and Flat Plate. Here $r_1 = r$, $r_2 = \infty$, and the above formulas reduce to $(b/4)^2 = 0.29Pr(c_1 + c_2)/l = 0.58Pr/El$, and

$$S^2_{max} = 0.35P/lr(c_1 + c_2) = 0.175PE/lr$$

Notation

R	= Reaction	S_v	= Vertical shearing unit stress
M	= Bending moment	Z	= Horizontal shearing unit stress
W	= Total distributed load	I	= Rectangular moment of inertia
w	= Distributed load per longitudinal unit	I_P	= Polar moment of inertia
		r	= Radius of curvature
P	= Concentrated load	i	= Slope
V or Q	= Total vertical shear	f	= Deflection
S	= Unit normal apparent stress	l	= Distance between supports

A **simple beam** is a bar resting on supports near its ends. A **cantilever beam** projects out beyond a support. To compute reactions and moments,

Theory of Flexure

A bent beam is shown in Fig. 25. The concave side is in compression and the convex side in tension. These are divided by the **neutral plane** of zero stress $A'B'BA$. The intersection of the neutral plane with the face of the beam is the **neutral line** or **elastic curve** AB. The intersection of the neutral plane with the cross-section is the **neutral axis** NN'.

It is assumed that a beam is prismatic, of a length at least 10 times its depth, and that the external forces are all at right angles to the axis of the beam and in a plane of symmetry, and that flexure is slight. Other assumptions are: (1) That the material is homogeneous, and obeys Hooke's law. (2) That stresses are within the elastic limit. (3) That every layer of material is free to expand and contract longitudinally and laterally under stress as if separate from other layers. (4) That the tensile and compressive moduli of elasticity are equal. (5) That the cross section remains a plane surface.

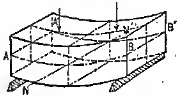

FIG. 25.

(The assumption of plane cross sections is only strictly true when the shear is constant or zero over the cross section, and when the shear is constant throughout the length of the beam.)

It follows then that: (1) The internal forces are in horizontal balance. (2) The **neutral axis contains the center of gravity** of the cross section, when there is no resultant axial stress. (3) The stress intensity varies directly with the distance from the neutral axis.

The moment of the elastic forces about the neutral axis, *i.e.*, the **stress moment** or **moment of resistance**, is $M = SI/c$, where S is an elastic unit stress at outer fiber whose distance from the neutral axis is c; and I is the rectangular moment of inertia about the neutral axis.

$$M = SI/c$$

This formula is for the **strength of beams**. For rectangular beams, $M = \frac{1}{6}Sbh^2$, where b = breadth, and h = depth. That is, the elastic **strength of beam sections** varies as follows:

(1) For equal width, as the square of the depth. (2) For equal depth, directly as the width. (3) For equal depth and width, directly as the strength of the material. (4) If span varies, then for equal depth, width and material, inversely as the span.

If a beam is cut in halves horizontally, the two halves laid side by side will carry only one-half as much as the original beam.

The term **section modulus** is given to the value of I/c, where c is the distance to the fiber carrying greatest stress. Moment of inertia of cross section = I.

Tables 6, 7, and 8 give the properties of various beam cross sections.

For **horizontal** or **longitudinal shear** in beams, see p. 439.

Relation of Moment and Shear. The shear V is the first differential of the bending moment M with respect to x. $dM/dx = V$. When M is a maximum, V is zero. In Fig. 23, $dM/dx = \frac{1}{2}W - wx$, which equals V.

Oblique Loading. It should be noted that Table 6 includes certain cases for which the horizontal axis is not a neutral axis, assuming the common case of vertical loading. The rectangular section with the diagonal as a

principal axes are axes with respect to which the moment of inertia is, respectively, a maximum and a minimum, and for which the product of inertia is zero. For symmetrical sections, axes of symmetry are always principal axes. For unsymmetrical sections, like a rolled angle section (Fig. 26), the inclination of the principal axis with the X axis may be found from the formula $\tan 2\theta = 2I_{xy}/(I_y - I_x)$, in which θ = angle of inclination of the principal axis to the X axis, I_{xy} = the product of inertia of the section with respect to the X and Y axes, I_y = moment of inertia of the section with respect to the Y axis, I_x = moment of inertia of the section with respect to the X axis. When this principal axis has been found, the other principal axis is at right angles to it.

Table 4. Approximate Safe Loads in Pounds on Steel Beams

l = length of beam; c = distance from support to nearest concentrated load; a = distance from support to end of beam.

Internal Moment beyond the Elastic Limit

Ordinarily, the expression $M = SI/c$ is used for stresses above the elastic limit, in which case S becomes an experimental coefficient S_R, the **modulus of rupture**, and the formula is empirical. The true relation is obtained by applying to the cross section a stress-strain diagram from a tension and compression test, as in Fig. 28. Figure 28 shows the side of a beam of depth d under flexure beyond its elastic limit; line 1–1 shows the distorted cross section; line 3–3, the usual rectilinear relation of stress to strain; and line 2–2, an actual stress-strain diagram, applied to the cross section of the beam, compression above and tension below. The neutral axis is then below the gravity axis. The outer material may be expected to develop greater ultimate strength than in simple stress, on account of the reinforcing action of material nearer the neutral axis that is not yet overstrained. This leads to an **equalization of stress** over the cross section. S_R exceeds the ultimate strength S_M in tension as follows: for cast iron, $S_R = 2S_M$; for sandstone, $S_R = 3S_M$; for concrete, $S_R = 2.2S_M$; for wood (green), $S_R = 2.3S_M$.

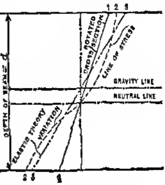

Fig. 28.

In the case of steel I beams, failure practically begins when the elastic limit in the compression flange is reached.

On account of support of adjoining material, the elastic limit in flexure S_p is also greater than in tension, depending upon the relation of breadth to depth of section. For the same breadth, the difference decreases with increase of height. No difference will occur in the case of an I beam, or with hard materials. Bauschinger quotes for soft steel plates, 1.27; Considère, 1.37; Hatt, 1.5 (*R. R. Gaz.*, 1899).

Wide plates will not expand and contract freely, and the value of E will be increased on account of side constraint. As a consequence of lateral contraction of the fibers of the tension side of a beam and lateral swelling of fibers at the compression side, the cross section becomes distorted to a trapezoidal shape, and the neutral axis is at the cg of the trapezoid. Strictly, this shape is one with a curved perimeter, the radius being r/m, where r is the radius of the neutral line of the beam, and m is Poisson's ratio.

Deflection of Beams

When a beam is subjected to bending, the fibers on one side elongate, while the fibers on the other side shorten (Fig. 29). These changes in length cause the beam to deflect. All points on the beam except those directly over the support fall below their original position, as shown by Fig. 25.

The **elastic curve** is the curve taken by the neutral axis. The radius of curvature at any point is

$$r = EI/M$$

A beam bent to a **circular curve** of constant radius has a constant bending moment.

Replacing r in the equation by its approximate geometrical value, $1/r = d^2y/(dx)^2$, the fundamental equation from which the elastic curve of a bent beam can be developed and the deflection of any beam can be obtained is,

$$M = EId^2y/(dx)^2 \text{ (approximate)}$$

This is a formula for **stiffness of beams**.

Substituting the value of M, in terms of x, and integrating once, gives the slope of the tangent to the elastic curve of the beam at point x, y; tan i =

horizontal axis (Table 9) is such a case. These cases must be handled by the principles of oblique loading.

Every section of a beam has two principal axes passing through the center of gravity, and these two axes are always at right angles to each other. The

Square, axis same as first rectangle, side $= h$; $I = h^4/12$; $I/c = h^3/6$; $r = 0.289h$.
Square, diagonal taken as axis: $I = h^4/12$; $I/c = 0.1179h^3$; $r = 0.289h$.

where C'' is a new constant $= n/m$. Other factors remaining the same, the **deflection varies directly as the stress and inversely as E.** If the span is constant, a shallow beam will submit to greater deformations than a deeper beam without exceeding a safe stress. If depth is constant, a beam of double span will attain a given deflection with only one-quarter the stress. Values of n, m, and C'' are as follows (for other values, see Table 2):

Beam	Load	n	m	C''
Cantilever	Concentrated at end	1	3	1/3
Cantilever	Uniform	2	8	1/4
Simple	Concentrated at center	4	48	1/12
Simple	Uniform	8	384/5	5/48
Fixed ends	Concentrated at center	8	192	1/24
Fixed ends	Uniform	12	384	1/32
One end fixed, One end supported	Concentrated at center	16/3	768/7	7/144
One end fixed, One end supported	Uniform	128/9	185	1/13
Simple	Uniformly varying, maximum at center	6	60	1/10

Graphical Relations

Referring to Fig. 31, the shear V acting at any section is equal to the total load on the right of the section, or

$$V = \int w dx$$

Since wdx is the product of w, a loading intensity (which is expressed as a vertical height in the load diagram), by dx, an elementary length along the horizontal, evidently *wdx is the area of a small vertical strip of the load* **diagram.** Then $\int wdx$ is the summation of all such vertical strips between two indefinite points. Thus, to obtain the shear in any section mn, find the area of the load diagram up to that section, and draw a second diagram called the **shear diagram,** any ordinate of which is proportional to the shear, or to the area in the load diagram to the right of mn. Since $V = dM/dx$,

$$\int V dx = M$$

By similar reasoning, a **moment diagram** may be drawn, such that the ordinate at any point is proportional to the area of the shear diagram to the right of that point. Since $M = EId^2f/(dx)^2$,

$$\int M dx = EI[(df/dx) + C] = EI(i + C)$$

if I is constant. Here C is a constant of integration. Thus i, the slope or grade of the elastic curve at any point, is proportional to the area of the moment diagram $\int M dx$ up to that point; and a **slope diagram** may be derived from the moment diagram in the same manner as the moment diagram was derived from the shear diagram.

If I is not constant, draw a new curve whose ordinates are M/I and use these M/I ordinates just as the M ordinates were used in the case where I was constant; that is, $\int (M/I) dx = E(i + C)$. The ordinate at any point *of the slope curve is thus proportional to the area of the M/I curve to the* right of that point. Again, since $iE = Edf/dx$,

$$\int iE dx = \int E df = E(f + C')$$

and thus the ordinate f to the elastic curve at any point is proportional to the area of the slope diagram $\int i dx$ up to that point. The equilibrium polygon may be used in drawing the **deflection curve** directly from the M/I diagram.

	$I=\frac{t}{4}\left(\frac{\pi B^3}{16}+B^2h+\frac{\pi Bh^2}{2}+\frac{2}{3}h^3\right)$ $h=H-\frac{1}{2}B$ $\frac{I}{c}=\frac{2I}{H+t}$		$\sqrt{\frac{I}{2\left(\frac{\pi B}{4}+h\right)t}}$

tion energy in the material of a beam in a length x is dU, and

$$U = \tfrac{1}{2}\int M^2dx/EI = \tfrac{1}{2}\int M di$$

where M is the moment at any point x, and di is the angle between the tangents to the elastic curve at the ends of dx. The values of resilience and deflection in special cases are easily developed from this equation.

Rolling Loads

Rolling or moving loads are those loads which may change their position on a beam. Figure 33 represents a beam with two equal concentrated moving loads, such as two wheels on a crane girder, or the wheels of a truck on a

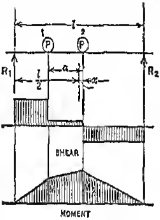

Fig. 33.

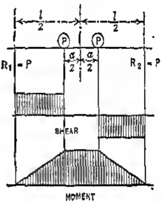

Fig. 34.

bridge. Since the maximum moment occurs where the shear is zero, it is evident from the shear diagram that the maximum moment will occur under a wheel. $x < a/2$:

$$R_1 = P\left(1 - \frac{2x}{l} + \frac{a}{l}\right)$$

$$M_2 = \frac{Pl}{2}\left(1 - \frac{a}{l} + \frac{2x}{l}\frac{a}{l} - \frac{4x^2}{l^2}\right)$$

$$R_2 = P\left(1 + \frac{2x}{l} - \frac{a}{l}\right)$$

$$M_1 = \frac{Pl}{2}\left(1 - \frac{a}{l} - \frac{2a^2}{l^2} + \frac{2x}{l}\frac{3a}{l} - \frac{4x^2}{l^2}\right)$$

M_2 max when $x = \tfrac{1}{4}a$,
M_1 max when $x = \tfrac{3}{4}a$.

$$M_{\max} = \frac{Pl}{2}\left(1 - \frac{a}{2l}\right)^2 = \frac{P}{2l}\left(l - \frac{a}{2}\right)^2$$

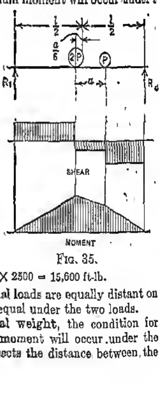

Fig. 35.

Example. Two wheel loads of 3,000 lb each, spaced on 5 ft centers, move on a span of l = 15 ft, x = 1.25 ft, and R_2 = 2,500 lb. ∴ Moment = 6.25 × 2500 = 15,600 ft-lb.

Figure 34 shows the condition when two equal loads are equally distant on opposite sides of the center. The moment is equal under the two loads.

If the **two moving loads are of unequal weight,** the condition for **maximum moment** is that the maximum moment will occur under the heavy wheel when the center of the beam bisects the distance between the

Calling the moments of inertia with respect to the principal axes, I_x' and I_y', the unit stress existing anywhere in the section at a point whose coordinates are x and y (Fig. 27) is $S = (My \cos \alpha / I_x') + (Mx \sin \alpha / I_y')$, in which M = bending moment with respect to the section in question, α = the angle which the plane of bending moment or the plane of the loads makes with the y axis, $M \cos \alpha$ = the component of bending moment causing bending about the principal axis which has been designated as the X axis, $M \sin \alpha$ = the component of bending moment causing bending about the principal axis which has been designated as the Y axis. The sign of the two terms for unit stress may be determined by inspection in the usual way, and the result will be tension or compression as determined by the algebraic sum of the two terms.

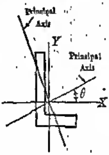

Fig. 26.

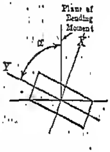

Fig. 27.

In general, it may be stated that when the plane of the bending moment coincides with one of the principal axes, then the other principal axis is the neutral axis. This is the ordinary case, in which the ordinary formula for unit stress may be applied. When the plane of the bending moment does not coincide with one of the principal axes, then the above formula for oblique loading may be applied.

Values apply to		wl	wl	wl^2	wl^2	l	l

* The numerical values given are coefficients of the expressions at the foot of each column.

$dy/dx = \int_0^x Mdx/EI$. Since i is usually small, $\tan i = i$, expressed in radians. A second integration gives the vertical deflection of any point of the elastic curve from its original position.

Example. In the cantilever beam shown in Fig. 29, the bending moment at any section $= -P(l - x) = EId^2y/(dx)^2$. Integrate and determine constant by the condition that when $x = 0$, $dy/dx = 0$. Then $EIdy/dx = -Plx + \frac{1}{2}Px^2$. Integrate again, and determine constant by the condition that when $x = 0$, $y = 0$. Then $EIy = -\frac{1}{2}Plx^2 + Px^3/6$. This is the equation of the elastic curve. When $x = l$, $y = f = -Pl^3/3EI$.

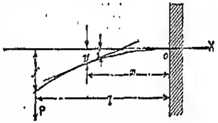

Fig. 29.

Deflection in general, f, may be expressed by the equation $f = Pl^3/mEI$, where m is a coefficient. See Tables 2 and 4 for values of f for beams of various sections and loadings. For coefficients of deflection of standard structural steel shapes, see steel manufacturers' handbooks.

Since I varies as the cube of the depth, the **stiffness,** or inverse deflection, of various **beams** varies, other factors remaining constant, inversely as the load, inversely as the cube of the span, and directly as the cube of the depth. This deflection is due to bending, but is increased by that due to vertical shear, especially in deep beams. For a **rectangular beam** with a center load P, the deflection due to vertical shear is $f' = Pl/4GA$, where G is the modulus of rigidity and A the area of cross section. The shear is assumed to be uniformly distributed. If the shear S_v is distributed according to the parabolic law, $f' = 3Pl/10GA$. If the **load is distributed,** the deflection due to vertical shear is one-third that due to same load concentrated at the center.

Usually, deflection due to shear is unimportant, but in case of **I-beam girders,** where the vertical shear in the web is large, f' may become important. Here the deflection due to shear $= Pl/4GA$, when the shear due to P is considered to act entirely on the web of area A.

Design of beams may be fixed either by consideration of strength or, if deformations must be low, by **stiffness.** Stiffness is controlled by design or by material (E).

When a load may pass by two paths to a support, the different paths take parts of the load in proportion to their stiffness.

Example (Fig. 30). Two wooden stringers—one (A) 8 × 16 in. in cross section and 20 ft in span, the other (B) 8 in. × 8 in. × 16 ft—carry the center load P_0 = 22,000 lb. Required, the load carried by each stringer. The deflections, f, of the two stringers must be equal. Load on $A = P_1$, and on $B = P_2$. $f = P_1l_1^3/48EI_1 = P_2l_2^3/48EI_2$. Then $P_1/P_2 = l_2^3I_1/l_1^3I_2 = 4$. $P_0 = P_1 + P_2 = 4P_2 + P_2$, whence $P_2 = 22{,}000/5 = 4{,}400$ lb and $P_1 = 4 \times 4400 = 17{,}600$ lb.

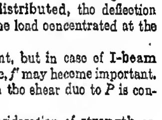

Fig. 30.

Relation between Deflection and Stress

Combine the formula $M = SI/c = Pl/n$, where n is a constant, P = load, and l = span, with formula $f = Pl^3/mEI$, where m is a constant. Then

$$f = C''Sl^2/Ec$$

Table 10. Beams of Uniform Strength (in Bending)

1. Fixed at One End, Load P Concentrated at Other End

Beam	Cross section	Elevation and plan	Formulas
1, 2 	Rectangle: width (b) constant, depth (y) variable	Elevation: 1, top, straight line; bottom, parabola. 2, complete parabola Plan: Rectangle	$y^2=\frac{6P}{bS_s}x$ $h=\sqrt{\frac{6Pl}{bS_s}}$ Deflection at A: $f=\frac{8P}{bE}\left(\frac{l}{h}\right)^3$
	Rectangle: width (y) variable, depth (h) constant	Elevation: Rectangle Plan: Triangle	$y=\frac{6P}{h^2S_s}x$ $b=\frac{6Pl}{h^2S_s}$ Deflection at A: $f=\frac{6P}{bE}\left(\frac{l}{h}\right)^3$
	Rectangle: width (z) variable, depth (y) variable: $\frac{z}{y}=k$ (const)	Elevation: Cubic parabola Plan: Cubic parabola	$y^3=\frac{6P}{kS_s}x$ $z=ky$ $h=\sqrt[3]{\frac{6Pl}{kS_s}}$ $b=kh$
	Circle: diam (y) variable	Elevation: Cubic parabola Plan: Cubic parabola	$y^3=\frac{32P}{\pi S_s}x$ $d=\sqrt[3]{\frac{32Pl}{\pi S_s}}$
2. Fixed at One End, Load P Uniformly Distributed over l			
	Rectangle: width (b) constant, depth (y) variable	Elevation: Triangle Plan: Rectangle	$y=x\sqrt{\frac{3P}{blS_s}}$ $h=\sqrt{\frac{3Pl}{bS_s}}$ $f=6\frac{P}{bE}\left(\frac{l}{h}\right)^3$

Thus, the five curves of load, shear, moment, slope, and deflection are so related that each curve is derived from the previous one by a process of graphical integration, and with proper regard to scales the deflection is thereby obtained.

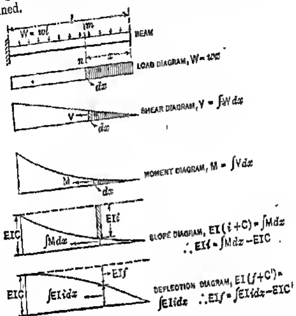

Fig. 31.

The vertical displacement of any point O_n (Fig. 32) in the elastic curve of a bent beam from the tangent line at any other point B, is Δf, and equals the area of the moment diagram between O'' and B'' times the distance X of the center of gravity of the area from O''. Or,

$$\Delta f = \text{Area } O''B''B'''O'''O'' \times X/EI$$

The angle d between the tangents at O_n and B equals the area of the moment diagram between O'' and B'' divided by EI. The intersection of the tangents at O_n and B is in the same vertical line as the center of gravity of the moment area between O'' and B''.

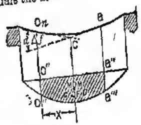

Fig. 32.

Resilience of Beams

The external work of a load gradually applied to a beam, and which increases from zero to P, is $\frac{1}{2}Pf$ and equals the **resilience** U. But, from formulas under "Relation between Deflection and Stress," p. 463, $P = nSI/cl$ and $f = nSl^2/mcE$, where n and m are constants that depend upon loading and supports, S = fiber stress, c = distance from neutral axis to outer fiber, and l = length of span. Substitute for P and f, and

$$U = \frac{n^2}{m}\left(\frac{k}{c}\right)^2 \cdot \frac{S^2V}{2E}$$

where k is the radius of gyration, and V the volume of the beam. For values of U, see Table 1.

The resilience of beams of similar cross section at a given stress is proportional to their volumes. The **internal resilience**, or the elastic deforma-

Table 10. Beams of Uniform Strength (in Bending)—(*continued*)

3. SUPPORTED AT BOTH ENDS, LOAD P CONCENTRATED AT POINT C

Beam	Cross section	Elevation and plan	Formulas
	Rectangle: width (b) constant, depth (y or y_1) variable	Elevation: Two parabolas, vertices at points of support Plan: Rectangle	$y^2 = \frac{6P(l-p)}{blS_s}x$ $y_1^2 = \frac{6Pp}{blS_s}x_1$ $h = \sqrt{\frac{6P(l-p)p}{blS_s}}$
LOAD P MOVING ACROSS SPAN			
	Rectangle: width (b) constant, depth (y) variable	Elevation: Ellipse, Major axis $= l$ Minor axis $= 2h$ Plan: Rectangle	$\frac{x^2}{\left(\frac{l}{2}\right)^2} + \frac{y^2}{\frac{3Pl}{2bS_s}} = 1$ $h = \sqrt{\frac{3Pl}{2bS_s}}$
4. SUPPORTED AT BOTH ENDS, LOAD P UNIFORMLY DISTRIBUTED OVER l			
	Rectangle: width (b) constant, depth (y) variable	Elevation: Ellipse Plan: Rectangle	$\frac{x^2}{\left(\frac{l}{2}\right)^2} + \frac{y^2}{\frac{3Pl}{4bS_s}} = 1$ $h = \sqrt{\frac{3Pl}{4bS_s}}$ Deflection at O: $f = \frac{1}{64}\frac{Pl^3}{EI} = \frac{3}{16}\frac{P}{bE}\left(\frac{l}{h}\right)^3$
	Rectangle: width (y) variable, depth (h) constant	Elevation: Rectangle Plan: Two parabolas with vertices at center of span	$y = \frac{3P}{S_sh^2}\left(x - \frac{x^2}{l}\right)$ $b = \frac{3Pl}{4S_sh^2}$

and depth d, $I/c = bd^2/6$; and $M = Sbd^2/6$. Thus, for a cantilever beam of rectangular cross section, under a load P, $Px = Sbd^2/6$. If b is constant, d^2 varies with x, and the profile of the shape of the beam will be a parabola, as Fig. 41. If d is constant, b will vary as x and the beam will be triangular in plan, as shown in Fig. 42.

Shear at the end of a beam necessitates a modification of the forms determined above. The area required to resist shear will be P/S_s in a can-

resultant of the loads and the heavy wheel. Figure 35 shows this position and the shear and moment diagrams.

When several wheel loads constituting a system occur, the several suspected wheels must be examined in turn to determine which will cause the greatest moment. The position for the greatest moment that can occur under a given wheel is, as stated, when the center of the span bisects the distance between the wheel in question and the resultant of all the loads then on the span. The position for maximum shear at the support will be when one wheel is passing off the span.

Constrained Beams

Constrained beams are those so held or "built in" at one or both ends that the tangent to the elastic curve remains fixed in direction. These beams are held at the ends in such a manner as to allow free horizontal motion, as illustrated by *Fig. 36. A constrained beam is stiffer* than a simple beam of the same material, on account of the modification of the moment by an end resisting moment. Figure 37 shows the two most common cases of constrained beams. See also Table 2.

Fig. 36.

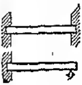

Fig. 37.

Continuous Beams

A continuous beam is one resting upon several supports which may or may not be in the same horizontal plane. The general discussion for beams holds for continuous beams. $S_vA = V$, $SI/c = M$, and $d^2f/dx^2 = M/EI$. The shear at any section is equal to the algebraic sum of the components parallel to the section of all external forces on either side of the section.

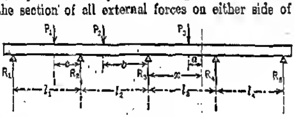

Fig. 38.

The bending moment at any section is equal to the moment of all external forces on either side of the section. The relations stated above between shear and moment diagrams hold true for continuous beams. The bending moment at any section is equal to the bending moment at any other section, plus the shear at that section times its arm, plus the product of all the intervening external forces times their respective arms. To illustrate (Fig. 38):

$$V_x = R_1 + R_2 + R_3 - P_1 - P_2 - P_3$$

$$M_x = R_1(l_1 + l_2 + x) + R_2(l_2 + x) + R_3x - P_1(l_2 + c + x) - P_2(b + x) - P_3a$$

$$M_x = M_3 + V_3x - P_3a$$

Table 16 gives the value of the moment at the various supports of a uniformly loaded continuous beam over equal spans, and it also gives the values of the shears on each side of the supports. Note that the shear is of opposite sign on either side of the supports and that the sum of the two shears is equal to the reaction.

Figure 39 shows the relation between the moment and shear diagrams for a uniformly loaded continuous beam of four equal spans (see Table 9). Table

thrust bearing plate might be considered a circular plate built in at the inner edge and loaded with a uniformly distributed load.

Let R = outside radius of plate. r = inside radius of plate. P = total load on plate, uniformly distributed along an edge, lb. p = load per sq in. of plate surface, lb. t = thickness of plate, in. E = modulus of elasticity, lb

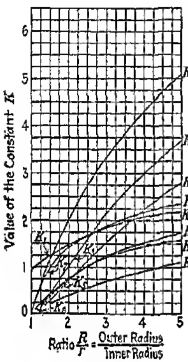

FIG. 48.—Values of K.

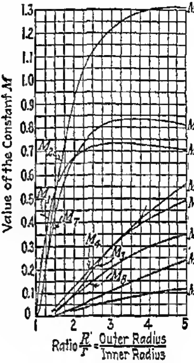

FIG. 49.—Values of M.

per sq in. S = maximum unit stress, lb per sq in., y = deflection of one edge of the plate with respect to the other, in.

For a plate loaded along the edge, $S = KP/t^2$; $y = MPR^2/Et^3$.

For a plate uniformly loaded $S = KpR^2/t^2$; $y = MpR^4/Et^3$.

The values of K and M depend on the ratio R/r and vary with the method of support of the two edges.

Values of K and M are given in Figs. 48 and 49. The constants are to be applied as follows:

Plate uniformly loaded

K_2, M_2, plate simply supported at inner edge, free at outer edge.

K_7, M_7, plate simply supported at outer edge, free at inner edge.

K_3, M_3, plate built in at inner edge, free at outer edge.

K_4, M_4, plate simply supported at outer edge, inner edge prevented from rotating.

K_5, M_5, plate built in at inner edge, outer edge prevented from rotating.

Plate loaded along edge

K_1, M_1, plate simply supported at outer edge, free at inner edge.

K_6, M_6, plate built in at inner edge, outer edge prevented from rotating.

K_8, M_8, plate built in at inner edge, outer edge free.

Continuous beams are stronger and much stiffer than simple beams. However, a small, unequal subsidence of piers will cause serious changes in sign and magnitude of the bending stresses, reactions, and shears.

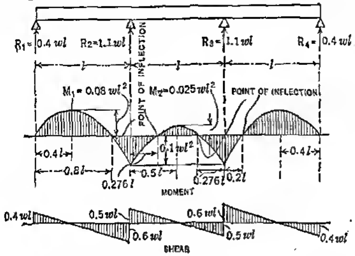

FIG. 40.

Maxwell's Theorem. When a number of loads rest upon a beam, the deflection at any point is equal to the sum of the deflections at this point due to each of the loads taken separately. Maxwell's theorem states that *if unit loads rest upon a beam at two points A and B, the deflection at A* due to the unit load at B equals the deflection at B due to the unit load at A.

Castigliano's theorem *states that the deflection of the point of application of an external force acting on a beam is equal to the partial derivative of the work of deformation with respect to this force.* Thus, if P be the force, f the deflection, and U the work of deformation, which equals the resilience,

$$dU/dP = f$$

According to the **principle of least work,** *the deformation of any structure takes place in such a manner that the work of deformation is a minimum.*

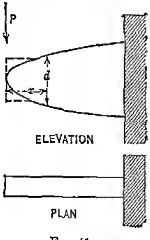

FIG. 41.

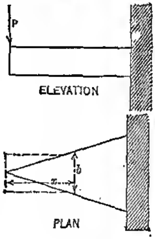

FIG. 42.

Beams of Uniform Strength

Beams of uniform strength so vary in section that the unit stress S remains constant, and I/c varies as M. **For rectangular beams,** of breadth b

9. Rectangular Plate Supported at the Periphery and Subjected to a Concentrated Load at the Center. (a and b = length and breadth, and $b/a = c$.) With the assumption made in (S),

$$S_{max} = 1.5K_1 \frac{c}{(1+c^2)} \frac{P}{t^2} \gtreqless S_s.$$

$K_1 = 1.75$ to 2.00 for cast iron. For $b = a$, $c = 1$ (square plate), and $S_{max} = 0.75K_1P/t^2 \gtreqless S_s$.

Deflection of Square Plates with Different Methods of Support. Deflection under uniformly distributed load $= f = 15b^4pK_2/\pi^4t^3E$. Values of K_2 are as follows:

Method of supporting plate	Center of plate K_2	Middle of unsupported edge K_2
2 edges supported, 2 rigidly fixed	0.134	.....
3 edges supported, 1 rigidly fixed	0.212	.....
4 edges supported, 0 rigidly fixed	0.310	.....
2 edges supported, 1 rigidly fixed, 1 not supported	0.430	0.825
3 edges supported, 1 not supported	0.602	0.915
2 edges supported, 2 not supported	0.994	1.110

Trapezoidal Plates. Calculations for these are made by assuming equivalent rectangular plates.

Flat Cylinder Heads with Flanged Edges (Fig. 51).

$$S_{max} = p\left\{K_1\frac{R}{t} + K_2\left[\frac{r - 0.5R\left(1 + \frac{R}{r}\right)}{t}\right]^2\right\}$$

in which R = radius of curvature of the flange and r = radius of head or attached cylinder, both in in.; p = internal pressure, in lb per sq in.

FIG. 51.

For steel heads riveted to the cylinder $K_1 = 0.5$, and $K_2 = 0.33$ to 0.38; for cast-iron heads integral with the cylinder, $K_1 = K_2 = 0.3$.

Curved Plates with Openings (Bach and Pfleiderer). With a single flue (Figs. 52 and 53) riveted into the plate, the greatest stress due to bending will be found at the flanges, and

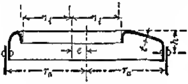

FIG. 52.

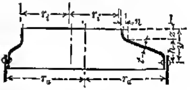

FIG. 53.

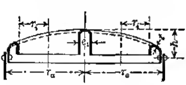

FIG. 54.

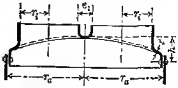

FIG. 55.

$$S_{max} = 0.45p\frac{r_a - r_i}{t^2}\left(r_a - r_i - 2e + \frac{5e^2}{h + 2e}\right).$$

NOTES.—1. $S_{s_{max}}$ at circumference. 2. $S_{s_{max}}$ at outer circumference. 3. $S_{s_{max}}$ at A; $S_{s_B} = 16M_t/\pi b h^2$. 4. $S_{s_{max}}$ at middle of side h; in middle of b, $S_s = 9M_t/2bh^2$. 5. $S_{s_{max}}$ at middle of side.

SPRINGS

It is assumed in the following formulas that the springs are in no case stressed beyond the elastic limit (*i.e.*, that they are perfectly elastic), and that they are subject to Hooke's law.

tilever and R/S_s in a simple beam. The dotted extensions in Figs. 41 and 42 show the changes necessary to enable these cantilevers to resist shear. The waste in material and extra cost in fabricating, however, make many of the forms impractical, except for cast iron.

Table 10 shows some of the simple **sections of uniform strength.** In none of these, however, is shear taken into account.

STRENGTH OF PLATES

Notation.

P = total load, lb.
p = load per unit area, lb per sq in.
t = thickness of plate, in.
S_{max} = maximum stress, lb per sq in.
S_s = safe stress, lb per sq in.
E = modulus of elasticity.
f = deflection, in.
K_1 and K_2 = coefficients.

The values of K_1 and K_2 are dependent upon the method of support and upon the initial force required to give a tight joint (to prevent leakage) before the load is applied. Cases 3 and 6 follow Grashof; the others, C. Bach. The formulas apply only within the elastic limit.

FIG. 43.

Flat Plates

1. Circular Plate Subjected to Uniformly Distributed Load.

FIG. 44.

$$S_{max} = K_1 r^2 p/t^2 \leqq S_s, \quad \text{and} \quad f = K_2 r^4 p/t^3 E.$$

For cast iron, K_1 = 0.8 (fixed edge) to 1.2 (freely supported); K_2 = 0.17 (fixed edge) to 0.60 (freely supported). For mild steel K_1 = 0.50 (not < 0.45) with fixed edge to 0.75 (not < 0.67) when freely supported.

In Fig. 43, S_{max} is at edge. In Fig. 44, S_{max} is at center. If the fixed ends deflect sufficiently to make the center and circumferential stresses equal, K_1 = 0.38, or not < 0.33.

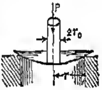

FIG. 45.

2. Circular Plate Loaded at the Center and Freely Supported at the Circumference (Fig. 45); P uniformly distributed over area πr_0^2.

$$S_{max} = \frac{3}{\pi}K_1\left(1 - \frac{2}{3}\frac{r_0}{r}\right)\frac{P}{t^2} \leqq S_s; \quad f = K_2\frac{r^2 P}{t^3 E}$$

For cast iron, K_1 = 1.5; K_2 = 0.4 to 0.5.

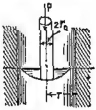

FIG. 46.

3. Circular Plate Loaded as in (2) but Fixed at the Circumference (Fig. 46).

$$S_{max} = \frac{1.365}{\pi}\frac{P}{t^2}\log_e\frac{r}{r_0} \leqq S_s;$$

$$f = \frac{0.6825}{\pi}\frac{r^2 P}{t^3 E} = 0.22\frac{r^2 P}{t^3 E}$$

FIG. 47.

4. Circular Plates with Concentric Circular Holes (Fig. 47).

The following formulas are used by the Westinghouse Electric & Mfg. Co. for the calculation of the strength of flat circular plates with holes (Fig. 47), such as diaphragms, flanges, and Kingsbury thrust-bearing plates, where the thickness is not over 15 percent of the difference in inside and outside diameters and where the deflection is not over half the thickness. The Kingsbury

5. Laminated Triangular Plate Spring (Fig. 61). If the triangular plate spring shown at I be cut into an even number ($= 2n$) of strips of equal width (in this case 8 strips of width $b/2$), and these strips be combined, a laminated spring will be formed whose carrying capacity will equal that of the original uncut spring; or $P = nbh^2S_s/6l$; $n = 6Pl/bh^2S_s$.

FIG. 61.

6. Laminated rectangular plate spring with leaf ends tapered in the form of a cubical parabola (Fig. 62); see (3) *ante*.

A plate which is "built in" is held rigidly and is subjected to both shearing force and bending moments. A plate which is "prevented from rotating" on an edge has zero slope in the radial direction at that edge but is permitted to move perpendicular to the plane of the plate; it is not subjected to shearing forces but only to bending moments. An example is the inner edges of a turbine diaphragm with a heavy hub and simply supported at the outer edge.

Example. A diaphragm having a clamped inner edge is loaded with a total load, P, 5.8 lb uniformly distributed along the outer edge.

$R = 1.12$ in.; $r = 0.5$ in.; $t = 0.017$ in.; $R/r = 2.25$; $E = 30 \times 10^6$ lb per sq in.
From Fig. 48, $K_1 = 0.9$; from Fig. 49, $M_1 = 0.12$.

The maximum stress, $S = K_1P/t^2 = 0.9 \times 5.8/(0.017)^2 = 18{,}000$ lb per sq in. The maximum deflection, $y = M_1PR^2/Et^3 = 0.12 \times 5.8 \times (1.12)^2/30 \times 10^6 \times (0.017)^3 = 0.006$ in.

5. Elliptical Plate Subjected to a Uniformly Distributed Load p (see Figs. 43 and 44).

Major axis $= 2a$; minor axis $= 2b$; ratio of axes $= b/a = c$.

$$S_{max} = K_1 \frac{b^2}{t^2} \frac{2p}{(1 + c^2)} \gtreqless S_t$$

For cast iron, $K_1 = 0.67$ (fixed) to 1.13 (freely supported).
For mild steel, $K_1 = 0.42$ (fixed) to 0.71 (freely supported).
For $c = 1$ (circle), $S_{max} = K_1b^2p/t^2$.

6. Elliptical Plate with Load P at the Center. Notation as in (5).

$$S_{max} = \frac{8}{5\pi} K_1 \frac{8 + 4c^2 + 3c^4}{3 + 2c^2 + 3c^4} c \frac{P}{t^2} \gtreqless S_t.$$

For cast iron, $K_1 = 1.50$ (fixed) to 1.67 (freely supported).
For $c = 1$ (circle), $S_{max} = 3K_1P/\pi t^2$.

7. Infinitely large plate subjected to a uniformly distributed load and supported at points distant a from each other (Fig. 50). For each single square,

$$S_{max} = 0.2275a^2p/t^2 \gtreqless S_t, \text{ and } f = 0.0284a^4p/t^3E.$$

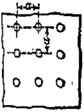

FIG. 50.

8. Rectangular Plate Supported at the Periphery and Subjected to a Uniformly Distributed Load. (a and b = length and breadth of plate; $b/a = c$.) For the calculation of stress along the diagonal, as in case (5) of an ellipse,

$$S_{max} = K_1 \frac{(b/2)^2}{t^2} \frac{2p}{(1 + c^2)} \gtreqless S_t$$

When $b = a$, $c = 1$ (square plate), and $S_{max} = 0.25K_1a^2p/t^2 \gtreqless S_t$.
For cast iron, $K_1 = 0.75$ (fixed) to 1.13 (freely supported).
For mild steel, $K_1 = 0.48$ (fixed) to 0.72 (freely supported).
If the plate is supported on two sides ($b = \infty$), the coefficient of a^2p/t^2 will be 0.50 (fixed) to 0.75 (freely supported).

Note. In cases (5) and (8), values of K_1 for mild steel are: for elliptical plates, 0.43 to 0.55 (max = 0.86); rectangular plates, 0.56 to 0.75 (max = 1.13). The maxima, which correspond to values for free support, are to be rarely used. The minimum value of K_1 corresponds to the case where the moment at the center equals the moment at the support, $M_{max} = pl^2/16$.

Tests on rectangular cast-iron plates at Case School of Applied Science (1896–1897), with load applied at center, give the following values for the breaking load W. For plates supported at the edges, $W = 276St^2/(l^2 + b^2)$; for plates with fixed edges, $W = 442St^2/(l^2 + b^2)$. The plates tested were 10 × 15 in., ½ to 1⅛ in. thick; modulus of rupture of the cast iron, 33,000 lb per sq in.

spring $= l$. See "Experiments on Helical Springs," by Benjamin and French, *Trans. A.S.M.E.*, **23**, p. 298.

For heavy closely-coiled **helical springs** the usual formulas are inaccurate and result in stresses greatly in excess of those assumed. See Wahl, "Stresses in Heavy Closely-coiled Helical Springs," *Trans. A.S.M.E.*, 1928. *In cases 10 to 12 and 15 to 18, the quantity k is unity for lighter springs and* has the stated values (supplied by Wahl) for heavy closely coiled springs.

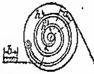

FIG. 65.

10. Spiral Coiled Spring of Rectangular Cross Section (Fig. 65).

$P = bh^2S_b/6rk$; $I = bh^3/12$; $U = Pf/2 = S_b^2V/6Ek^2$;
$f = ra = Plr^2/EI = 12Plr^2/Ebh^3 = 2rlS_b/hEk$.

For heavy closely-coiled springs $k = (3c - 1)/(3c - 3)$, where $c = 2R/h$ and R is the minimum radius of curvature at the center of the spiral.

11. Cylindrical Helical Spring of Circular Cross Section (Fig. 66).

$P = \pi d^3S_b/32rk$; $I = \pi d^4/64$; $U = Pf/2 = S_b^2V/8Ek^2$;
$f = ra = Plr^2/EI = 64Plr^2/\pi Ed^4 = 2rlS_b/dEk$.

For heavy closely-coiled springs, $k = (4c - 1)(4c - 4)$ where $c = 2r/d$.

12. Cylindrical Helical Spring of Rectangular Cross Section (Fig. 67).

$P = bh^2S_b/6rk$; $I = bh^3/12$; $U = Pf/2 = S_b^2V/6Ek^2$;
$f = ra = Plr^2/EI = 12Plr^2/Ebh^3 = 2rlS_b/hEk$.

For heavy closely-coiled springs, $k = (3c - 1)/3c - 3)$, where $c = 2r/h$.

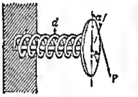

FIG. 66.

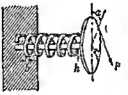

FIG. 67.

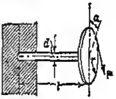

FIG. 68.

Springs Subjected to Torsion

The statements made concerning coiled springs subjected to bending apply also to (13) and (14).

13. Straight Bar Spring of Circular Cross Section (Fig. 68).

$P = \pi d^3S_v/16r = 0.1963d^3S_v/r$; $U = Pf/2 = S_v^2V/4G$;
$f = ra = 32r^2lP/\pi d^4G = 2rlS_v/dG$.

14. Straight Bar Spring of Rectangular Cross Section (Fig. 69).

$P = 2b^2hS_v/9r$; $K = b/h$; $U = Pf/2 = 4S_v^2V(K^2 + 1)/45G$ (maximum when $K = 1$);
$f = ra = 3.6r^2lP(b^2 + h^2)/b^3h^3G = 0.8rlS_v(b^2 + h^2)/bh^2G$.

Springs Loaded Axially Either in Tension or Compression

[Note. For springs 15 to 18, r = mean radius of coil; n = number of coils.]

15. Cylindrical Helical Spring of Circular Cross Section (Fig. 70).

$P = \pi d^3S_v/16rk = 0.1963d^3S_v/rk$; $U = Pf/2 = S_v^2V/4Gk^2$;
$f = 64nr^3P/d^4G = 4\pi nr^2S_v/dGk$.

With two flues (Figs. 54 and 55),

$$S_{max} = 22p\frac{r_a - 1.5r_i}{t^2}\left(r_a - r_i - 2e + \frac{5e^2}{h + 2e}\right).$$

In computing h (Fig. 53), assume $s = 1.5$ to $2t$.

TORSION

Under torsion, a bar (Fig. 56) is twisted by a couple of the value Pp. Elements of the surface become helices of angle d, and a radius rotates through an angle a in a length l, both d and a being expressed in radians. S_v = shearing unit stress at distance r from center; I_P = polar moment of inertia; G = shearing modulus of elasticity. It is assumed that the cross sections remain plane surfaces. The strain on the cross section is wholly tangential, and is zero at the center of the section. $ld = ra$.

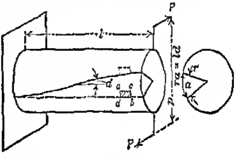

FIG. 56.

In the case of a **circular cross section**, the stress S_v increases directly as the distance of the strained element from the center.

The polar moment of inertia I_P for any section may be obtained from $I_P = I_1 + I_2$, where I_1 and I_2 are the rectangular moments of inertia of the section about any two lines at right angles to each other, through the center of gravity.

The **external twisting moment** M_t is balanced by the internal resisting moment.

For strength, $M_t = S_v I_P/r$.

For stiffness, $M_t = aGI_P/l$.

The torsional resilience $U = \frac{1}{2}Ppa = S_v^2 I_P l/2r^2G = a^2GI_P/2l$.

The state of stress on an element taken from the surface of the shaft, as in Fig. 57, is pure shear. Pure tension exists at right angles to one 45 deg helix and pure compression at right angles to the opposite helix.

Reduced formulas for shafts of various sections are given in Table 11.

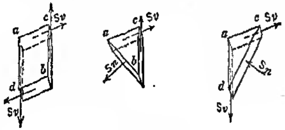

FIG. 57.

Failure under torsion in brittle materials is a tensile failure at right angles to a helical element of the surface. Plastic materials twist off squarely. Fibrous materials separate in long strips.

Torsion of Non-circular Sections. When a section is not circular, the unit stress no longer varies directly as the distance from the center. Cross-sections become warped, and the greatest unit stress usually occurs at a point on the perimeter of the cross-section *nearest* the axis of twist. There is no stress at the corners of square and rectangular sections, and the analyses become complex.

Notation:

P = Safe load, lb.
f = Deflection for a given load, P, in.
l = Length of spring, in.
V = Volume of spring, cu in.
S_s = Safe stress (due to bending), lb per sq in.
S_v = Safe shearing stress, lb per sq in.
U = Resilience, in.-lb.

For values of E, see p. 418. Benjamin and Hoffman (in "Machine Design") recommend the following values for S_v, G and E: For spring brass wire, S_v = 45,000 to 60,000; G = 6,000,000; E = 9,000,000. For spring steel, tempered, S_v = 75,000 to 115,000; G = 12,000,000 to 15,000,000: E = 30,000,000.

The work in inch-pounds performed in deflecting a spring from 0 to f (spring duty) is $U = Pf/2 = S_s^2V/CE$. This is based upon the assumption that the deflection is proportional to the load. C is a constant dependent upon the shape of the springs.

The time of vibration T (in seconds) of a spring (weight not considered) is equal to that of a simple circular pendulum whose length l_0 equals the deflection f (in ft) that is produced in the spring by the load P. $T = \pi\sqrt{l_0/g}$, where g = acceleration of gravity in ft per sec.[2]

Springs Subjected to Bending

(See first case in Table 2, p. 451)

1. Rectangular Plate Spring (Fig. 58).

$$P = bh^2S_s/6l; \quad I = bh^3/12; \quad U = Pf/2 = VS_s^2/18E;$$
$$f = Pl^3/3EI = 4Pl^3/bh^3E = 2l^2S_s/3hE.$$

2. Triangular Plate Spring (Fig. 59). The elastic curve is a circular arc.

$$P = bh^2S_s/6l; \quad I = bh^3/12; \quad U = Pf/2 = S_s^2V/6E;$$
$$f = Pl^3/2EI = 6Pl^3/bh^3E = l^2S_s/hE.$$

3. Rectangular plate spring with end tapered in the form of a cubical parabola (Fig. 60). The elastic curve is a circular arc. P, I, and f same as for triangular plate spring (Fig. 59). $U = Pf/2 = S_s^2V/9E$.

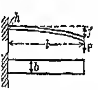

Fig. 58.

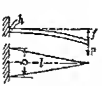

Fig. 59.

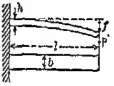

Fig. 60.

The strength and deflection of single-leaf flat springs of various forms are given (R. A. Bruce, *Am. Mach.*, July 19, 1900) by the formulas $h = al^2/f$ and $b = cPl/h^2$. The volume of the spring is given by $V = vlbh$. The values of the constants a and c and the resilience in inch-pounds per cubic inch are given in Table 12, both in terms of the safe stress S_s and for stated specific values of S_s and E. Values of v are given also.

4. Compound (Leaf or Laminated) Springs. If several springs of rectangular section are combined, the resulting compound spring should (1) form a beam of uniform strength that (2) does not open between the joints while bending (*i.e.*, elastic curve must be a circular arc). Only the type immediately following meets both requirements, the others meeting only the second requirement.

7. Laminated Trapezoidal Plate Spring with Leaf Ends Tapered. (Fig. 63.) The ends of the leaves are trapezoidal in form and are tapered according to the *formula*

$$z = h/1 + \sqrt[3]{\frac{b_1}{b}\left(\frac{a}{x} - 1\right)}$$

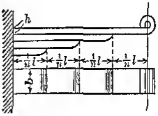

FIG. 62.

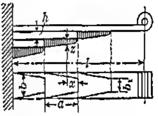

FIG. 63.

8. Semielliptic Springs (for locomotives, horse-drawn and automobile trucks, etc.). *Referring to Fig. 64, the load $2P$ (lb) acting on the spring center band produces a tensional stress $P/\cos a$ in each of the inclined shackle links.* This is resolved into the vertical force P and the horizontal force $P \tan a$, which together produce a bending moment $M = P(l + p \tan a)$. The *equations* given in (1), (2), and (3) apply to curved as well as straight springs. The bearing force $= 2P = (2nbh^2/6)[S_s/(l + p \tan a)]$, and the deflection $= (6l^2/nbh^3)P(l + p \tan a)/E = l^2S_s/hE$.

In addition to the bending moment, the leaves are subjected to the tensional force $P \tan a$ and the transverse force P, which produce in the upper leaf an additional stress $S = P \tan a/bh$, as well as a shearing stress to be calculated according to p. 465.

In determining the number of leaves n in a given spring, allowance should be made for an excess load on the spring caused by the vibration. This is usually made by decreasing the allowable stress about 15 percent.

The foregoing does not take account of initial stresses caused by the band. For more detailed information, see "The Design of Automobile Springs," by E. R. Morrison, *Machinery*, Jan., 1910.

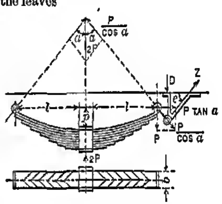

FIG. 64.

9. Elliptic Springs. Safe load P(lb) $= nbh^2S_s/6l$, where $l = \frac{1}{2}$ distance between bolt eyes (less $\frac{1}{2}$ length of center band, where used); deflection f (in.) $= 4l^2S_sK/hE$, where

$$K = \frac{1}{(1 - r)^3}\left[\frac{1 - r^2}{2} - 2r(1 - r) - r^2 \log_e r\right]$$

r being the number of full-length leaves $\div$ total number (n) of leaves in the spring. All dimensions in inches. For semielliptic springs, the deflection is only half as great. Safe load $= nbh^2S_s/3l$. (J. B. Peddle, *Am. Mach.*, Apr. 17, 1913.)

Coiled Springs. In these, the load is applied as a couple Pr which turns the spring while winding or holds it in place when wound up. If the spindle is not to be subjected to bending moment, P must be replaced by two equal and opposite forces ($P/2$) acting at the circumference of a circle of radius r. The formulas are the same in both cases. The springs are assumed to be fixed at one end and free at the other. The bending moment acting on the section of least resistance is always Pr. The length of the straightened

If, as in certain classes of masonry construction, the material cannot withstand tensile stress and thus no tension can occur, the center of moments (Fig. 75) is taken at the center of stress. For a rectangular section, P acts at distance k from the nearest edge. Length under compression $= 3k$, and $S_m = \frac{2}{3}P/hk$. For a circular section, $S_m = [0.372 + 0.056(k/r)]P/k\sqrt{rk}$, where r = radius and k = distance of P from circum-

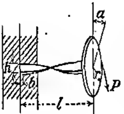
For heavy closely-coiled springs, $k = [(4c - 1)/(4c - 4)] + 0.615/c$, where $c = 2r/d$.

16. Cylindrical Helical Spring of Rectangular Cross Section (Fig. 71).

$P = 2b^2hS_v/9rk$; $K = b/h$; $U = Pf/2 = 4S_v^2V(K^2 + 1)/45GK^2$ (maximum when $K = 1$);

$f = 7.2\pi nr^3P(b^2 + h^2)/b^3h^3G = 1.6\pi nr^2S_v(b^2 + h^2)/bh^2Gk$.

For heavy closely-coiled springs, $k = [(4c - 1)/(4c - 4)] + 0.615/c$, where $c = 2r/b$.



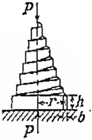


Fig. 69. Fig. 70. Fig. 71. Fig. 72. Fig. 73.

17. Conical Helical Spring of Circular Cross Section (Fig. 72).

l = length of developed spring; d = diameter of wire; r = maximum mean radius of coil.

$P = \pi d^3S_v/16rk = 0.1963d^3S_v/rk$; $U = Pf/2 = S_v^2V/8Gk^2$;

$f = 16r^2lP/\pi d^4G = 16nr^3P/d^4G = rlS_v/dGk = \pi nr^2S_v/dGk$.

For heavy closely-coiled springs, $k = [(4c - 1)/(4c - 4)] + 0.615/c$, where $c = 2r/d$.

18. Conical Helical Spring of Rectangular Cross Section (Fig. 73).

$K = b/h$; $P = 2b^2hS_v/9rk$; $U = Pf/2 = 2S_v^2V(K^2 + 1)/45GK^2$ (maximum when $K = 1$);

$f = 1.8r^2lP(b^2 + h^2)/b^3h^3G = 1.8\pi nr^3P(b^2 + h^2)/b^3h^3G$.

$= 0.4rlS_v(b^2 + h^2)/bh^2Gk = 0.4\pi nr^2S_v(b^2 + h^2)/bh^2Gk$.

For heavy closely-coiled springs, $k = [(4c - 1)/(4c - 4)] + 0.615/c$, where $c = 2r/b$.

19. Truncated Conical Springs (Types 17 and 18). The formulas under (17) and (18) apply for truncated springs. In calculating deflection f, however, it is necessary to substitute $(r_1^2 + r_2^2)$ for r^2, and $\pi n(r_1 + r_2)$ for πnr, r_1 and r_2 being respectively the greatest and least mean radii of the coils.

Note. The preceding formulas for various forms of coiled springs are sufficiently accurate when the cross section dimensions are small in comparison with the radius of the coil, and for small pitch. Springs (15) to (19) are for either tension or compression.

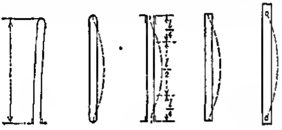
Safe working loads and deflections of cylindrical helical springs of round steel wire in tension or compression are given in Table 13. The table is based on the formulas given in (15) ante. d = diameter of steel, in.; D = pitch diameter (center to center of wire), in.; P = safe working load for given unit stress, lb; f = deflection of 1 coil for safe working load, in.

The table is based on the values of unit stress indicated, and G = 12,500,000. For any other value of unit stress, divide the tabular value by the unit stress used in the table and multiply by the unit stress to be used in the design. For any other value of G, multiply the value of f in the table by 12,500,000 and divide by the value of G chosen. **For square steel**, multiply values of P

critical load at which equilibrium no longer obtains. The ratio of length to radius of gyration, or **slendernsss ratio,** at which a column begins to fail by buckling, is between 100 and 120. Such columns are computed by Euler's formula. Few structural columns fail as long columns.

Short columns with values of l/r less than 100 begin to fail when the combination of direct stress and bending stress reaches the yield point of the material. The actual failure is dependent upon the homogeneity of the material, the straightness of the column, and the eccentricity of loading, all of which control bending stresses. Failure of built-up columns begins with a local crippling at some part of the column. Such elements are not susceptible of calculation, and short columns of this kind are to be computed by empirical formulas which are, however, modeled on rationally derived forms.

Failure of columns also depends upon the condition of their ends, as shown in Fig. 78: (*a*) **Free-ended** column, as a mast with a terminal load; (*b*) **round-ended,** as a spherical bearing; (*c*) fixed-ended, when rigidly con-



a b c d e

FIG. 78.

nected to a rigid support; (*d*) **square-ended,** when a square-ended column abuts upon a support; and (*e*) a combination of rounded and fixed ends as a pin. The theoretical curves of flexure are shown by dotted lines. Columns of types (*c*), (*d*), and (*e*) are common. Ideal conditions are only obtained practically in free-ended columns. Structural columns have various degrees of freedom. The elements controlling the strength of columns ars so indsterminate that refined analysis is misapplied.

Long Columns

Notation. A = Area of cross section; P = load; l = length; r = radius of gyration = $\sqrt{I/A}$; f = deflection; I = rectangular moment of inertia; S = unit axial stress.

Euler's Formula. A perfect or ideal column with a straight axis, of uniform material, and loaded in the direction of its axis, would fail in direct compression like a short block. On account of imperfections, a sudden lateral deflection will occur under some critical load on a long column, which will then be no longer in equilibrium. The **critical load,** acting with a continually increasing leverage, will continue to bend the column until it fails by buckling. This critical load, P, for rounded ends, is given by Euler's formula (published in 1759) as follows:

$$P = \pi^2EI/l^2$$

The assumptions made in deriving this formula are: (1) that the shortening of the column may be neglected; (2) that the bent length of arc is equal to the

be the allowable unit stress for designing, and should be the ultimate compressive strength where ultimate load is required.

Table 17. Values of the Coefficient K in Rankine's Formula

Material	Both ends fixed	Fixed and rounded	Both ends rounded	Fixed and free
Timber	1/3000	1.95/3000	4/3000	16/3000
Cast iron	1/5000	1.95/5000	4/5000	16/5000
Wrought iron	1/36000	1.95/36000	4/36000	16/36000
Steel	1/25000	1.95/25000	4/25000	16/25000

Tetmajer's experiments on round-ended columns (*Z.V.d.I.*, 1896, p. 1404) show that K varies with the material of the column and with the value of l/r. For wrought iron, K varied from 0.000448 to 0.000136; for steel, from 0.000370 to 0.000130. Tetmajer's recommended values for K are as follows:

	l/r	K
Cast iron	20–150	0.00070
Wrought iron	20–250	0.00016
Soft steel	20–250	0.00014
Wood	20–200	0.00023

Tetmajer's formula for ultimate loads on round-ended columns is

$$S = S_c[1 - a(l/r) + b(l/r)^2]$$

Table 18. Values for Tetmajer's Formula for Short Columns

Materials	S_c	a	b	Limits of l/r	
				Min	Max
Cast iron	110,000	0.01546	0.00007	5.0	80
Wrought iron	43,000	0.00426	0.0	10.0	112
Hard steel	48,000	0.00185	0.0	....	90
Soft steel	44,000	0.00368	0.0	10.0	105
Wood	4,200	0.00662	0.0	1.8	100

Straight-line Formula for Columns. Plotted results of tests yield a straight-line relation between the load at failure and the slenderness ratio l/r. T. H. Johnson's formula is $P/A = S - C(l/r)$, where S is the unit strength of a very short column, and C is a constant obtained by drawing the straight line tangent to a curve representing Euler's formula at a point where $l/r = 150$. The values recommended for use in this formula are given in Table 19. For designing, S and C should be divided by a proper factor of safety.

Table 19. Constants for Johnson's Straight-line Column Formula

Kind of column		S lb per sq in.	C	Limit of l/r
Wrought iron:	Flat ends	42,000	128	218
	Hinged ends	42,000	157	178
	Round ends	42,000	203	138
Steel:	Flat ends	52,500	179	195
	Hinged ends	52,500	220	159
	Round ends	52,500	284	123
Cast iron:	Flat ends	80,000	438	122
	Hinged ends	80,000	537	99
	Round ends	80,000	693	77
Oak:	Flat ends	5,400	28	128

by 1.06, and values of f by 0.75. **For brass,** take S_s = 10,000 to 20,000, and multiply values of f by 2 (Howe).

When designing a spring for continuous work, as a car spring, a low unit stress should be chosen; for intermittent working a higher value may be used.

Examples of Use of Table 13. (1) Required the safe load (P) for a spring of ⅜ in. round steel with a pitch diameter (D) of 3½ in. In the line headed D, under 3½, is given the value of P, or 678 lb. This is for a unit stress of 115,000 lb per sq in. The load, P, for any other unit stress may be found by dividing the 678 by 115,000 and multiplying by the unit stress to be used in the design. To determine the number of coils, this spring would need to compress (say) 6 in. under a load of (say) 678 lb, take the value of f under 678, or 0.938, which is the deflection of one coil under the given load. Therefore 6/0.938 = 6.4, say 7, equals the number of coils required. The spring will therefore be 2⅝ in. long when closed (7 × ⅜), counting the working coils only, and must be 8⅝ in. long when unloaded. Whether there is an extra coil at one end which does not deflect will depend upon the details of the particular design. The deflection in the above example is for a unit stress of 115,000 lb per sq in. The rule is, divide the deflection by 115,000 and multiply by the unit stress to be used in the design.

(2) A 7/16 in. steel spring of 3½ in. outside diameter has its coils in close contact. How much can it be extended without exceeding the limit of safety? The maximum safe load for this spring is found to be 1074 lb and the deflection of one coil under this load is 0.810 in. This is for a unit stress of 115,000 lb per sq in. Therefore 0.810 is the greatest admissible opening between any two coils. In this way, it is possible to ascertain whether or not a spring is overloaded, without knowledge of the load carried.

ECCENTRIC LOADS

When **short blocks** are loaded **eccentrically** in compression or in tension, *i.e.*, not through the center of gravity (cg), a combination of axial and bending stress results. The maximum unit stress S_m is the algebraic sum of these two unit stresses.

In Fig. 74 a load P acts in a line of symmetry at the distance e from cg; r = radius of gyration. The unit stresses are (1) S_c, due to P, as if it acted through cg, and (2) S_b, due to the bending moment of P acting with a leverage of e about cg. Thus unit stress S at any point y is

$$S = S_c \pm S_b$$
$$= (P/A) \pm Pey/I$$
$$= S_c(1 \pm ey/r^2).$$

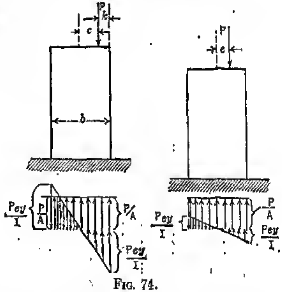

Fig. 74.

y is positive for points on the same side of cg as P, and negative on the opposite side. **For a rectangular cross section** of width b, the maximum stress $S_m = S_c(1 + 6e/b)$. When P is outside the middle third of width b and is a compressive load, tensile stresses occur.

For a **circular cross section** of diameter d, $S_m' = S_c(1 + 8e/d)$. The stress due to the weight of the solid will modify these relations.

Note. In these formulas e is measured from the gravity axis, and gives tension when e is greater than ⅙ the width (measured in the same direction as e), for rectangular sections; and when greater than ⅛ the diameter for solid circular sections.

M_t. $S = My/I = 8Pl/\pi d^3$, and $S_s = 16M_t/\pi d^3$ for a circular shaft. S and S_s combine (Fig. 81) to produce internal normal (S_n) and tangential (S_t) unit stresses on an interior plane (see p. 443). In Fig. 81, S_n, and S_t vary with the angle d. S_n is a maximum when $\cot 2d = -S/2S_s$, and S_t is a maximum when $\tan 2d = +S/2S_s$. The maximum apparent stresses are:

$$S_n = \tfrac{1}{2}S \pm \sqrt{S_s^2 + (\tfrac{1}{2}S)^2} \qquad S_t = \sqrt{S_s^2 + (\tfrac{1}{2}S)^2}$$

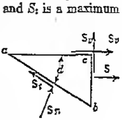

FIG. 81.

These formulas also apply to any case of normal stress combined with shear, as when a bolt is under tension and shear, or when the material of a beam is under tension (or compression) and shear. When S is tension, use (+) sign in order to find the maximum tensile stress S_n, and use (−) sign to find the maximum compressive stress S_n. For strength under combined stresses, see p. 443.

Combined Torsion and Longitudinal Force

A common case is the shaft of a vertical turbine. The longitudinal force is then compression. If W be the weight carried on the shaft in pounds, d the shaft diameter in inches, H the horsepower transmitted, and n the rpm,

$$S_n = \frac{2W}{\pi d^2} + \sqrt{\frac{321{,}000^2H^2}{n^2d^6} + \frac{4W^2}{\pi^2d^4}} \qquad S_t = \sqrt{\frac{321{,}000^2H^2}{n^2d^6} + \frac{4W^2}{\pi^2d^4}}$$

Combined Flexure and Longitudinal Force

Figure 82 shows a bar under flexure due to transverse and longitudinal loads. The maximum fiber stress S (Fig. 82) is made up of S_s, due to the direct action of load P, and S_b, due to the entire bending moment M. M is the algebraic sum of two bending moments, M_1 due to longitudinal load (+ for compression and − for tension), and M_2 due to transverse load. $M = M_2 \pm M_1$. Here $M_1 = Pf$ and $f = CS_bl^2/Ec$.

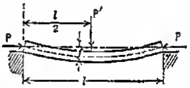

FIG. 82.

For the Case of Longitudinal Compression. $S_bI/c = M_2 + CPS_bl^2/Ec$, or $S_b = M_2c/(I - CPl^2/E)$. The maximum stress is $S = S_b + S_s$ compression. The constant C for the case of Fig. 82 is derived from the equations $Pl/4 = S_bI/c$ and $f = Pl^3/48EI$. Solving for f; $f = \frac{1}{12}S_bl^2/Ec$, or $C = \frac{1}{12}$. For a beam supported at the ends and uniformly loaded, $C = \frac{5}{48}$. Other cases can be similarly calculated.

For the Case of Longitudinal Tension. $M = M_2 - Pf$, and $S_b = M_2c/(I + CPl^2/E)$. The maximum stress is $S = S_b + S_s$, tension.

A common method for computing stresses on eccentrically loaded columns consists in adding to the uniform stress, P/A, the additional stresses due to column action, $(P/A)(Kl^2/r^2)$, as given by Rankine's formula, p. 491, and that due to eccentricity, $(P/A)(ey/r^2)$. Thus,

Total stress $= \dfrac{P}{A}\left(1 + \dfrac{ey}{r^2} + \dfrac{Kl^2}{r^2}\right)$ when $S_b = \dfrac{P}{A}\left(1 + \dfrac{ey}{r^2}\right)$ = stress due to flexure, and $S_c = \dfrac{P}{A}\left(1 + \dfrac{Kl^2}{r^2}\right)$ = stress due to longitudinal load.

ference. For a **circular ring,** S = average compressive stress on cross-section produced by P; e = eccentricity of P; z = length of diameter under compression (Fig. 76). Values of z/r and of the ratio of S_{max} to average S are given in Tables 14 and 15.

Chimney Problem. Weight of chimney = 563,000 lb; e = 1.56 ft; outside diam of chimney = 10 ft 8 in.; inside diam = 6 ft 6½ in. Overturning moment = Pe = 878,000 ft-lb, r_1/r = 0.6. e/r = 0.29. This gives $(z/r) > 2$. Therefore, the entire area of the base is under compression. Area under compression = 55.8 sq ft; I = 546; S = (563,000/55.8) ± (878,000 × 5.33)/546 = 18,700 (max) and 1,500 (min) lb compression per sq ft. From Table 15, by interpolation, S_{max}/S_{avg} = 1.85 ∴ S_{max} = (563,000/55.8) × 1.85 = 18,685 lb per sq ft.

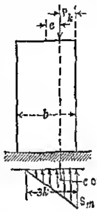

FIG. 75.

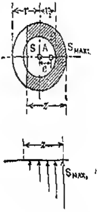

FIG. 76.

The kern is the area around the center of gravity of a cross section within which any load applied will produce stress of only one sign throughout the entire cross-section. Outside the kern, a load produces stresses of different sign. Figure 77 shows kerns (shaded) for various sections.

For a **circular ring,** the radius of the kern $r = D[1 + (d/D)^2]/8$.

For a **hollow square** (H and h = lengths of outer and inner sides), the kern is a square similar to Fig. 77(a), where

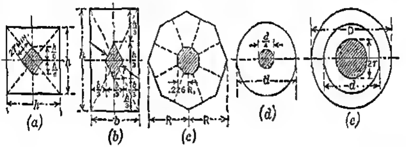

FIG. 77.

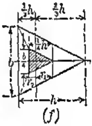
$$r_{min} = \frac{H}{6}\frac{1}{\sqrt{2}}\left[1 + \left(\frac{h}{H}\right)^2\right] = 0.1179H\left[1 + \left(\frac{h}{H}\right)^2\right]$$



For a **hollow octagon** [R_o and R_i = radii of circles circumscribing the outer and inner sides; thickness of wall = $0.9239(R_o - R_i)$], the kern is an octagon similar to Fig. 77(c), where $0.2256R$ becomes $0.2256R_o[1 + (R_i/R_o)^2]$.

COLUMNS

A column differs from a tension bar in that any non-uniform yielding in the cross section brings about further yielding. This non-uniform yielding is not serious in short blocks, but is serious in columns.

Columns are divided for analysis into **long columns** and **short columns,** in both of which initial inequalities introduce serious bending.
